The energy input for midwinter snowmelt is primarily provided by sensible heat flux from the warm air over the melting snowpack because the radiation input is relatively small in midwinter. The sensible heat flux gain during a warm spell is partially offset by the latent heat flux loss associated with evaporation or sublimation. As such, the rate of midwinter melt is much less than that of spring melt driven by radiation, even under a warmer climate. Therefore, the midwinter release of meltwater from the snowpack is also smaller unless it is enhanced by rain on snow. As a result, the meltwater release rate may be small enough to be absorbed by the unsaturated frozen soil. In such case, the meltwater will wet the surface soil and refreeze during the subsequent cold spell, and repeated melt-refreeze cycles will reduce the soil infiltrability. If the soil is still frozen and the snowcover is left on the ground in the spring, the high snowmelt rate driven by both radiation and sensible heat flux can generate a large volume of runoff.

The climate-change effects on the hydrology of seasonally frozen catchments depend on the complex interaction between changes in air temperature and precipitation. Therefore, the prediction of climate-change effects requires careful consideration of energy and water transfer processes in the atmosphere-snow-soil system and its feedback with vegetation covers and land management practices.

Climate-change effects on permafrost hydrology

Warming and subsequent thawing of permafrost may impact hydrology in several ways (Walvoord and Kurylyk, 2016). A thickening of the active layer may result in a lowering of the water table in the active layer and thereby a deepening of active layer water flow paths (Fig. 6). Warming may lead to higher potential evapotranspiration, while a deeper water table and increased connectivity may limit the water available for actual evapotranspiration (Sjöberg et al., 2021; Andresen et al., 2020). The net effect of warming and permafrost thaw on evapotranspiration is so far poorly constrained.

Fig. 6 Impact of permafrost on flow paths and water table (conceptual). Panel (a) illustrates local flow paths with a high groundwater table perched by permafrost, while panel (b) shows how without permafrost longer flow paths are present.

The formation of a supra-permafrost talik directly below the seasonal frost may allow for groundwater flow during the cold season (Walvoord et al., 2019). In general, thawing permafrost is expected to lead to increased connectivity and storage of (liquid) groundwater. Such catchment-scale changes may be detectable in historical streamflow records. Increases in winter streamflow have been observed in rivers across the Arctic and have been interpreted as signs of reduction in catchment-scale permafrost (St. Jacques and Sauchyn, 2009). The storage-discharge relationship of a catchment has also been leveraged to infer changes in permafrost from analyzing changes in the shape of the hydrograph during recession flow periods (Lyon and Destouni, 2010). Changes in stream water chemistry, such as decreasing DOC concentration or rising concentrations of weathering products have been interpreted as signs of deeper water flow paths due to thawing permafrost (O'Donnell et al., 2021).

Concluding remarks

The permanent or seasonal presence of ice is a distinct feature of soil hydrology in cold regions. While the thermodynamic principles governing soil freezing and thawing are reasonably well established in laboratory settings, our understanding of field-scale processes has many challenges. The infiltrability of frozen soil has a strong influence on the partitioning of snowmelt water into infiltration and runoff, which in turn affects the magnitude and timing of water inputs to river systems. The frozen soil infiltrability is strongly dependent on the complex interaction between soil matrix and macropore networks, as well as the history of repeated freeze-thaw and midwinter infiltration events. To advance knowledge on the effects of frozen soil on hydrological processes, an important challenge is to improve our capability to predict field-scale soil infiltrability in various environments.

The presence of permafrost has profound implications on the partitioning of surface and subsurface water storage and flow paths. Water tables perched near the ground surface by permafrost forces flow through soil layers with typically high hydraulic conductivity and organic content. Thawing of permafrost may lead to increases in groundwater connectivity and storage, deeper and slower groundwater flow paths, and shifts in water chemistry. At the catchment scale, such changes in storage and connectivity are challenging to observe and current understanding is to a large extent built on theoretical assumptions.

Abstract

Soil water content can be sensed by counting thermal (energy at room temperature) neutrons that are scattered from collisions of more energetic (fast) neutrons with the nuclei of atoms. Repeated collisions reduce the energy of fast neutrons until they are at thermal energy, a process called moderation. Hydrogen atoms, mainly found in soil water, are more effective moderators than are most elements found in soils, so the count of thermal neutrons is a good indicator of the amount of water in soil. Fast neutron sources can be man-made or natural (cosmic ray collisions with atoms). Neutron scattering approaches can be used for access tube measurements or larger-scale near-surface measurements using the cosmic ray neutron scattering method.

Key points

- The neutron moisture meter (NMM, also called neutron probe) is an accurate ($\text{RMSE} < 0.01 \text{ m}^3 \text{ m}^{-3}$) method for assessing soil and vadose zone profile water content and changes in storage in profiles that may extend to $> 100 \text{ m}$ depth.
- The NMM senses a much larger soil volume ($14,000\text{--}65,000 \text{ cm}^3$) than do in situ soil water sensors that rely on electromagnetic measurements ($60\text{--}600 \text{ cm}^3$).
- The NMM uses a man-made radioactive source of fast neutrons that prohibits its unattended use.
- Hydrogen in the soil, mostly in soil water, preferentially slows fast neutrons until they reach a thermal energy state.
- The source and detector of thermal neutrons are placed together in a probe that is lowered into the soil through an access tube.
- The count of thermal neutrons increases with the soil water content.
- The cosmic ray neutron scattering (CRNS) method employs at least two detectors that are placed at a height of approximately 1 m above the soil surface, one to sense thermal neutrons and one to sense fast neutrons.
- The CRNS method estimates the soil water content in a much larger (radius of $130\text{--}240 \text{ m}$) but also much more ill-defined volume of soil.
- Depth of CRNS sensing ranges from 15 cm to 70 cm but most of the sensed volume is at less than 20-cm depth.

Introduction

The method of sensing soil water content by counting slow neutrons scattered back to a detector was conceived of due to understanding of neutron interactions with matter developed in the 1940s (Belcher et al., 1950; Pieper, 1949), and an effective neutron moisture meter (NMM) using a man-made radioactive source of energetic neutrons was demonstrated by Grant (1975). Seven decades later, the neutron scattering method used in access tubes remains a competitive method for repeated determination of changes in soil profile water content (Evett et al., 2008; IAEA, 2000) because it is nondestructive, has a large sensing volume that reduces variability compared to other methods, can be field calibrated for accurate sensing, works successfully to depths not easily attained with other methods (e.g., $> 100 \text{ m}$), and works well in stony soils and cracking clays in which other methods work poorly. The large volume sensed means that a given precision can be obtained with fewer replicates than are required for other methods such as the capacitance and time domain methods, that soil disturbance during access tube installation has minimal effect on results (unlike electronic sensor methods), and that field calibration is successful because volumetric soil samples can be obtained from within the volume measured by the probe at each depth. The technology is mature with a wide literature base describing

applications and problems. The Cosmic Ray Neutron Scattering (CRNS) method, which relies on naturally occurring neutrons, was conceived by Desilets and Zreda (2003) and developed into a useful method more recently (Desilets and Zreda, 2013; Franz et al., 2012a, 2012b; Rosolem et al., 2013). The two methods have much in common but also are distinctly different in what they can reliably sense and in how they may be used.

How it works

The neutron thermalization method relies on a source of fast neutrons (mean energy of 5 MeV) and a detector of slow neutrons (~ 0.025 eV or 300 K). Fast neutron sources are either man-made as in the case of the neutron moisture meter (NMM) or natural as in the case of the CRNS method. Energetic neutrons emitted from a NMM source ($\sim 10^9$ /s) are either slowed through repeated collisions with the nuclei of atoms in the soil (scattering and thermalization) or are absorbed by those nuclei, the latter being one source of interference with the method. A small fraction of scattered neutrons will enter the detector. Of these, an even smaller fraction ($\sim 10^3$ /s) will be slowed to thermal (room temperature) energy levels and will be detected. Soil density and chemical composition affect the concentration of thermalized neutrons around the detector. The most common atoms in soil (aluminum and silicon) scatter neutrons with little energy loss because they have much greater mass than a neutron. However, the energy of a neutron is halved if it hits a hydrogen nucleus, because the mass of the hydrogen nucleus is the same as that of the neutron. On average, 19 collisions with hydrogen are required to thermalize a neutron, a process called moderation. Other relatively efficient neutron moderators are carbon, nitrogen, and oxygen (about 120, 140 and 150 collisions, respectively). On the time scales of common interest in water and environmental management, changes in soil carbon and nitrogen content are minor and have little effect on changes in the concentration of thermal neutrons, although absolute quantities of these elements and of oxygen in the soil may affect the calibration of the neutron method as is the case with soil with large concentrations of CaCO_3 . Also, on these time scales, changes in soil hydrogen and oxygen content occur mainly due to changes in soil water content. The detection of thermal neutrons is thus most affected by changes in water content; and volumetric water content can be accurately and precisely related to the count of thermal neutrons through calibration of the NMM. For the NMM the count of slow neutrons is positively related to the soil water content. For the CRNS method, the source of fast neutrons is natural collisions of cosmic rays with atomic nuclei in the atmosphere near the ground. The CRNS detector is positioned above ground and detects thermal neutrons scattered back into the atmosphere from the soil, vegetation, and from water in the air. The back scattered slow neutron count is reduced as water content of the soil, vegetation and atmosphere increase, resulting in an inverse relationship between soil water content and thermal neutron count for the CRNS method.

Interferences

The organic matter content of soil affects the NMM calibration because hydrogen and carbon effectively thermalize neutrons. Also, organic matter and most clays contain important amounts of hydrogen, some not in the form of water, that may not be driven off by heating to 105 °C (the standard temperature for drying soil samples). Separate calibrations thus are often required for soil layers that differ in organic matter or clay content from layers above or below. In arid or semi-arid zones, many soils have layers rich in CaCO_3 and CaSO_4 that require separate calibration (Van Bavel et al., 1956). Boron, cadmium, chlorine, iron, fluorine, lithium and potassium are atoms that absorb neutrons, and soils or soil horizons that contain large or fluctuating amounts of such elements will require separate calibrations or adjustments in data interpretation. For example, separate calibration may be required for soils with appreciable concentrations of boron, chloride salts or iron, such as Oxisols or soils rich in magnetite. These interferences with the neutron scattering method have been rather thoroughly discussed in the literature for the NMM but are less well understood for the CRNS method. Neither method is much affected by soil salinity within the range survivable by plants.

Neutron moisture meters

Typical forms of NMM equipment include: (1) a profiling meter with a source—detector pair assembled into a cylindrical probe that is lowered to user-chosen depths into a hole in the soil, and (2) a flat-based meter that is placed on the soil surface with the source and detector fixed at separate locations inside the base of the meter. The surface meter senses a volume that is roughly hemispherical and extends into the soil for a distance that decreases as soil water content and soil density increase, and which varies from ~ 0.15 m in wet soil to ~ 0.3 m in dry soil (Van Bavel et al., 1956). The precision is less than can be attained with a profiling NMM meter; and it suffers even more when soil moisture changes greatly with depth near the surface (Van Bavel et al., 1961), a common occurrence. Nakayama and Allen (1990) reported that stringent conditions are required for good precision including: (1) flattening the surface to fit the meter bottom with no air gaps, (2) marking the measurement site so that the meter can be repeatedly placed in identical position, and (3) using a neutron absorber shield made of cadmium around the meter (except for the bottom) to reduce effects of surrounding vegetation. Even with these conditions, however, the strong depth dependency of calibration coefficients and the inability to accurately estimate the depth of reading led to great uncertainty as to the accuracy of measurements.

The profiling NMM (Fig. 1B) is more commonly used. It is operated at user-chosen depths in the soil. The hole is lined with a cylindrical access tube in order to protect the probe and ensure a constant hole diameter. A cable connects the probe to a counter,

Fig. 1 (A) Cross-sectional schematic of a profiling neutron moisture meter in place on top of a depth control stand (Evelt et al., 2003). The stand is in place over an access tube that has been inserted into the soil. The probe is locked in the meter shield and standard counts may be taken in this position so long as vegetation is absent for a distance of at least 3 m. For the dimensions given here, to measure at 10-cm depth, the probe must be lowered 104 cm through the stand and into the access tube. Clamps placed on the cable ensure that the lowering distance is maintained for that a subsequent reading depths. Dimensions vary for meters of different manufacture. (B) Photograph of a Campbell Pacific Nuclear NMM resting on a depth control stand and with the probe locked in the shield. The stand is itself resting on a base plate that has a length of access tube welded normal to its center to prevent the stand from toppling. Cable clamps are visible.

data storage and display module. The cable allows the probe to be lowered into the tube and stopped at intervals to measure the thermal neutron concentration. Common probe diameters are 38 mm and 51 mm. The readout and control unit are typically attached to a block of high-density polyethylene that acts as the instrument shield. The probe is locked into this shield when not in use. Probes from different manufacturers have different physical arrangements of the source of fast neutrons and the detector, and this arrangement affects the calibration (McCauley and Stone, 1972). The source may be directly beneath the detector or is centered around or on one side of it. The source-detector geometry in modern NMMs has little effect on the attainable accuracy and precision (Allen et al., 1993; Dickey et al., 1993; Evelt and Steiner, 1995). The source in modern meters is a mixture of beryllium and americium-241 with an activity ranging from 0.4 GBq to 1.9 GBq. The ^{241}Am decays, emitting an alpha particle, which then is absorbed by a Be atom, which in turn produces ^{12}C and a fast neutron in the nuclear reaction: $^9\text{Be}(\alpha, n)^{12}\text{C}$. The sensed volume is approximately a sphere with radius, R (cm), that decreases with increases in volumetric water content (θ_v , $\text{m}^3 \text{m}^{-3}$), according to

$$R = 15(\theta_v)^{-1/3} \quad (1)$$

About 95% of the measured slow neutrons are from this volume (IAEA, 1970).

Access tubes and depth control

Successfully employed access tubing materials include stainless steel, mild steel, galvanized steel, polyvinyl chloride (PVC), polycarbonate, and polyethylene plastics, and aluminum. Calibration is affected by all access tube materials but more so by the hydrogen in all plastics and the neutron absorber chlorine in PVC tubes. The neutron absorber iron affects calibration in steel tubes, while aluminum is nearly transparent to neutrons. Thus, it is imperative that a NMM be calibrated in the same tubing as will be used in the field. Although calibration precision decreases slightly if plastic tubes are used (Allen et al., 1993), precision and accuracy are much more dependent on the tube installation and calibration methods employed than on tube material. Recommendations for installation of access tubes are given in Hignett and Evelt (2002) and Evelt et al. (2008) give recommendations for choice of access tube material and installation methods.

Access tubes are commonly installed vertically with a few cm of tubing protruding above the soil surface, mostly to prevent soil and water from entering the tube, which is further ensured by use of a tube covering or plug. The common practice of placing the NMM on top of the access tube near the soil surface before lowering the probe for readings is not recommended for two reasons. First, when the NMM is placed near the soil surface, the shield in the meter body may influence near-surface counts to a degree that depends strongly on the height of the meter above the soil (Stone et al., 1993). Second, in field use, the height of access tubes above the soil is likely to change with tillage, rainfall induced settling, erosion or deposition, or other factors, resulting in an equivalent change in the depth of probe placement. For readings above 0.3-m depth, centimeter scale differences in the depth of the probe will

strongly influence the neutron count and the calibration equation due to loss of neutrons to the atmosphere (Grant, 1975; Van Bavel et al., 1961).

Evetts et al. (2003) showed how these problems are addressed using a depth control stand. The stand comprises a length of metal tubing, the same size as the access tube, fixed to a 0.2-m length of slightly larger tubing that is in turn supported by a foot resting directly on the soil surface (Fig. 1A). The larger diameter of the lower length of tubing allows it to be slipped over the top of an access tube. Cable stops are arranged to achieve the desired depths of placement of the probe, thus maintaining the reading depths at exact distances relative to the soil surface. Standard counts taken with the probe locked in the shield are routinely taken during NMM calibration and field use. Standards taken with the meter too close to the soil surface will vary with the water content of the soil (Allen and Segura, 1990; Dickey, 1990). The stand described is tall enough (>80 cm) to be suitable for taking standard counts without interference from soil water content, with the NMM mounted on the stand and the probe locked in the meter shield. Using these tools, accurate calibration and subsequent readings may be achieved at depths as shallow as 10 cm (Table 1) (Evetts and Steiner, 1995).

NMM statistics

The Poisson probability distribution describes the random process of neutron emission from the source. For processes described by the Poisson distribution, a series of counts over equal time periods will have a standard deviation that is equal to the square root of the mean value. One result of this fact is that the coefficient of variation of counts can be reduced by increasing the counting time. The sample mean, m , is computed as

$$m = \frac{1}{N} \sum_{i=1}^N x_i \quad (2)$$

where x_i is the value of a single count taken over a time period and N is the number of counts (all taken with the probe in one position and for the same length of time). The sample standard deviation, s , is computed as

$$s = \left[\frac{1}{N-1} \sum_{i=1}^N (x_i - m)^2 \right]^{1/2} \quad (3)$$

For a properly operating meter with the probe in a constant environment, the mean value of the ratio $s/(m)^{1/2}$, called the Chi ratio, should be close to unity. The χ^2 statistic can be used to describe the probability distribution of the ratio:

$$\frac{s}{m^{1/2}} = \left[\frac{\chi^2}{N-1} \right]^{1/2} \quad (4)$$

Values of χ^2 (Chi-squared) for a given probability level (P) are given in statistical tables for different values of $(N-1)$. Writing the right-hand-side of Eq. (4) for the upper and lower limits of χ^2 , we can obtain upper and lower values of the Chi ratio for the chosen probability level and number of samples. For example, for 32 samples and a 95% probability level, the values of χ^2 are 17.5 for $P = .975$ and 48.1 for $P = .025$; and the Chi ratio from Eq. (4) should be between 0.75 and 1.25 about 95 times in every hundred. Some meters divide the count by a fixed number in order to reduce the displayed count to a reasonably small value. In computing Chi ratios for such meters, the user should first multiply the recorded counts by the factor that the meter used to reduce them. Modern NMMs have a standard count function that takes many counts and computes the mean standard count and Chi ratio, making it easy for the user to obtain those values for use in calibration, quality control, and everyday computation of water contents from a calibration equation. Chi ratio values that are repeatedly more than unity or less than unity are cause for concern and likely will require repair of the NMM, as will large and consistent deviations of the standard count from the mean of previous standard counts. A consequence of the Chi ratio tending to unity is that the standard deviation decreases quickly as count time and the value of m increases (Fig. 2).

Table 1 Calibrations of water content (θ_v , $\text{m}^3 \text{m}^{-3}$) vs. count ratio (C_R) for the Amarillo fine sandy loam using the methods in Evetts and Steiner (1995), including a depth control stand.

Depth (cm)	Equation	RMSE	r^2	N
10	$\theta_v = 0.014 + 0.2172C_R$	0.004	0.997	6
30–190	$\theta_v = -0.063 + 0.2371C_R$	0.007	0.988	44
30–90	$\theta_v = -0.066 + 0.2421C_R$	0.008	0.988	24
110–190	$\theta_v = -0.057 + 0.2299C_R$	0.006	0.992	20

RMSE is root mean squared error, N is the number of samples, and r^2 is the coefficient of determination for the regression analysis. From Evetts SR and Steiner JL (1995) Precision of neutron scattering and capacitance type moisture gages based on field calibration. *Soil Science Society of America Journal* 59: 961–968. doi: 10.2136/sssaj1995.03615995005900040001x.

Fig. 2 Decrease in the standard deviation of the mean count as the count time increases for a particular model of neutron moisture meter. Accuracy of field calibration with this meter is typically $<0.01 \text{ m}^3 \text{ m}^{-3}$. One can use a count time of 1 min to maintain equivalent precision.

NMM calibration, accuracy, and representativity

Manufacturers provide NMM calibration equations based on measurements taken in standard samples, but these are seldom useful for soil water content determination (e.g., Dickey, 1990). Calibration of NMMs involves taking neutron count measurements, x , with the probe at different depths below the soil surface and standard counts, x_s , with the probe locked in the meter shield, and then computing the count ratio, C_R , defined as

$$C_R = x/x_s \quad (5)$$

for each depth. Correlating the measured count ratio values with independently determined volumetric water content, θ_v ($\text{m}^3 \text{ m}^{-3}$), values results in a calibration equation. For modern meters and the normal range of values of soil water content, the calibration is linear and of the form

$$\theta_v = b_0 + b_1 C_R \quad (6)$$

where b_0 and b_1 are the calibration coefficients as determined by linear regression, Count ratio values are used because the source activity and thus counts will decline over time, and because the detector efficiency is somewhat temperature dependent (Evet, 2000a). Recommendations for taking standard counts are given in Hignett and Evett (2002) and Evett et al. (2008), as are recommendations for field calibration using the wet site—dry site method of Evett and Steiner (1995). Careful field calibrations done using the wet site—dry site method and the depth control stand should attain root mean squared errors $<0.01 \text{ m}^3 \text{ m}^{-3}$ and r^2 values greater than 0.9, even for depths near the surface (e.g., 10 cm in Table 1).

Although the NMM has been proven to be an accurate means of assessing soil profile water storage, changes in storage, and crop water use (using the soil water balance equation), the individual depth-wise water content values should be well understood as being representative of a large volume, not a point. Fig. 3 illustrates this with a comparison of depth-wise water content data from two NMM access tubes compared with the depth-wise water content values from a system of three profiles of TDR sensors (see Time Domain Reflectometry article). Both the NMM and TDR sensors were calibrated for the soil in question. The top five TDR data are from depths of 2, 6, 10, 20, and 30 cm while the top two NMM values are from depths of 10 cm and 30 cm. As can be seen, the 10-cm NMM value provides close to an average of TDR water contents from the surface to 30 cm, and the 30-cm NMM values provide close to an average of TDR water contents from the 20 cm to 50 cm depths. Despite the differences in depth-wise values, profile water content calculated from the NMM and TDR methods over multiple dates was strongly correlated ($r^2 = 0.95$). Due to the large sensing volume of the NMM relative to that of electromagnetic sensing technologies, such as TDR, the number of neutron probe access tubes needed to represent the soil profile water content and change in storage for a small (tens of meters) experimental plot may be as small as one (Evet et al., 2009). For larger fields, several neutron probe access tubes may be needed to represent the field mean water content change in storage for accurate calculation of field mean evapotranspiration (Evet et al., 2012).

NMM safety and use considerations

Safety concerns include radiation safety and back and knee strains incurred during repeated bending and kneeling to operate meters placed on access tubes. The depth control stand described above has virtually eliminated physical injuries where it is used because it allows users to work standing up. Due to the small levels of radioactivity involved, the ALARA (As Low As Reasonably Achievable) principle of reducing exposure guides most radiation safety rules. Radiation received by users may be reduced by increasing distance

Fig. 3 Profiles of depth-wise water content values from a NMM used in two access tubes and of the mean of three nearby TDR sensors at each depth. All were in a monolithic weighing lysimeter. Both NMM and TDR sensors had soil-specific calibrations.

from the meter, decreasing time spent near the meter, and increasing shielding. The probe should always be locked into the shield except when it is lowered into an access tube. Users should be made aware that the source emits radiation at all times, even when the meter is turned off and batteries removed. Guidelines for ALARA use of the NMM are found in [Evetts \(2000b\)](#). The International Atomic Energy Agency maintains an Internet site of useful information on radiation safety and hazardous materials transport (HYPERLINK "<http://www.iaea.org/worldatom/>" <http://www.iaea.org/worldatom/>).

Due to regulation, the NMM method is not usable for automatic measurements. Due to its large measurement volume, the method is inappropriate where detailed vertical definition is required. This can be particularly important near the surface where water content often changes rapidly with depth. In such cases, the NMM can be used for deeper measurements in conjunction with time domain reflectometry (TDR) measurement of the near-surface soil water content ([Evetts et al., 1993](#)). The time and effort required to install access tubes and calibrate for each soil type is nontrivial. There is also a substantial cost for the equipment and for necessary training and licenses to handle and transport radioactive materials.

Radiation safety concerns are not pertinent to the CRNS method because the radiation involved is naturally occurring. The cost of CRNS equipment is larger than that of NMM equipment but CRNS equipment is easily transported for mobile applications without radiation safety concerns.

Cosmic ray neutron scattering

The COSMOS (Cosmic Ray Soil Moisture Observing System) cosmic ray-induced neutron detection system was introduced in 2008–2010 ([Desilets et al., 2010](#); [Shuttleworth et al., 2010](#); [Zreda et al., 2008](#)). Many later publications have referred to the method used in COSMOS as the Cosmic Ray Neutron Scattering (CRNS) method. The method has been used to map surface soil water variations using a tomographic approach ([Franz et al., 2015](#)), and is promising for testing of satellite remote sensing-based soil water products ([Crow et al., 2012](#)). The flux rate of fast neutrons produced by collisions of cosmic rays with atoms in the atmosphere near the ground is known to be affected by altitude and natural fluctuations in the cosmic ray flux rate, so the method depends on continuous knowledge of the cosmic ray flux rate at the specific geographic location and altitude where the method is deployed. This knowledge is provided by operators of CRNS networks. CRNS equipment typically consists of, at minimum, two thermal neutron detectors placed approximately 1 m above the ground surface, one of which is unshielded and acts to count thermalized neutrons that pass into it. The other detector is shielded with high density polyethylene plastic that prevents thermal neutrons from passing through to the detector. Fast neutrons are scattered in the shield such that some of them pass into the detector, which thus acts to count the fast neutron flux. The fast neutron flux is reduced as soil water content increases because fast neutrons are thermalized through interaction with hydrogen in the soil water. Thus, the fast neutron count is inversely proportional to soil water content (Eq. 7). Neutron detections are counted by a high-speed electronic counter, the data are temporarily stored in an embedded computer, and then transmitted, typically by satellite transmission, to the network base station where data are stored, adjusted for cosmic ray intensity at the CRNS unit location, and made available to the user. The CRNS method may be deployed as a static installation (e.g., [Fig. 4](#)) or as a mobile, even backpack, deployment.

Fig. 4 CRNS equipment installed at a large weighing lysimeter at the center of a 220-m square corn field. The inset photo shows a COSMOS CRNS unit with thermal (left) and fast neutron (right) detectors, counters, and embedded computer. In the field photograph the COSMOS unit is the white vertical rectangular object to left of center.

The CRNS method responds to the soil water content near the surface and to the near-surface atmospheric humidity and vegetation over a large area (100 s of meters). Assuming that atmospheric humidity effects are negligible, soil water content, θ_v , at time t may be inferred using

$$\theta_v(t) = \rho_{bd} \{a_o [F(t) \times N/N_0(t)] - a_1\}^{-1} - a_2\} - \theta_{LW} - \theta_B - \theta_{SOC} \quad (7)$$

where ρ_{bd} is the mean dry soil bulk density, N is the time dependent fast neutron count rate, N_0 is the time dependent fast neutron count over dry soil, θ_{LW} is the soil lattice water content, θ_B is the biomass water content equivalent, θ_{SOC} is the soil organic carbon water content equivalent, and a_o , a_1 and a_2 are fitting parameters with values of 0.0869, 0.3720, and 0.1236, respectively. The correction factor, $F(t)$, accounts for variable absolute humidity, solar activity, and absolute humidity of the air (IAEA, 2017). Rosolem et al. (2013) described a correction for absolute humidity of the air.

The depth of soil sensed is specific to the soil and is inversely related to its water content. Shuttleworth et al. (2010), using Monte Carlo analysis, determined an effective depth of sensing to be <0.15 m for wet soil and >0.7 m for dry soil; and they determined that an effective sensing diameter was between 650 m and 700 m and relatively independent of soil water content. Later studies have shown considerable smaller radii and depth of sensing (Franz et al., 2012a; Köhli et al., 2015). Except quite near the installation site, the CRNS method does not respond to soil water changes deeper than ~20 cm. Köhli et al. (2015) found that the sensing radius was in the range of 130–240 m depending on soil water content, vegetation, and humidity of the air; and that the depth of sensing ranged from 15 cm to 83 cm, decreasing quickly and exponentially with distance from the sensor. For example, in experiments at Bushland, Texas, the CRNS did not respond to subsurface drip irrigation amounts ranging from 12 mm to 50 mm where the drip tapes were installed at depths of 32–34 cm. Recent work has attempted to reduce the spatial weighting of CRNS data, which is caused by the radially decreasing sensing depth (Scheffele et al., 2020), thereby turning it into an unweighted integral soil water content over the support volume that would be used more easily in other applications. The reduction of spatial weighting did, however, require the installation of at least one and preferably three or more accurate soil water sensing profiles at distances <100 m from the CRNS and with three or more sensors at depths from just below the surface (e.g., 5 cm) down to at least 50-cm depth. Several studies have focused on the influence of above-ground biomass on the CRNS signal (Hornbuckle et al., 2012; Franz et al., 2013; Bogena et al., 2013) and found that the hydrogen in biomass decreases the thermal neutron intensity and the accuracy of the CRNS. Subsequently, research investigated the use of empirical corrections (Baatz et al., 2015) and the ratio of thermal to fast neutrons to correct for biomass (Tian et al., 2016; Jakobi et al., 2018; Vather et al., 2020). The precision of N is described by Eq. (3), so precision may be improved by increasing either the counting time or using additional or improved detectors, both of which increase the total count and so reduce the standard deviation. Mobile CRNS equipment typically includes multiple or improved detectors for this reason. For static installations, precision may be improved by integrating counts over 12-h or longer periods, for example by using a running average as was done in COSMOS.

Despite the impediments discussed here, the CRNS method is rapidly maturing and is recognized as an important approach to bridging the gap between satellite derived soil water content data products and the point-scale or nearly point-scale soil water data provided by networks of in-situ electromagnetic sensors and the neutron probe. Integration of data from networks of CRNS units

and networks of in situ sensors may be a powerful tool for better understanding of soil-plant-atmosphere dynamics and watershed hydrology (Fersch et al., 2020).

Outlook

Advances in neutron detection continue and will have a strong impact on the neutron scattering method for soil water monitoring for multiple reasons, including appreciable reduction of the cost relative to commercially available ^3He and BF_3 based detectors. Boron lined proportional counters have proven effective (Weimar et al., 2020). This detector comprises a layer of $^{10}\text{B}_4\text{C}$ deposited on a copper foil that is used to line the inside of an Al tube. Multiple tubes may be used to increase neutron count rate and decrease SD. The detector is not yet commercially available. Flynn et al. (2021) described a ^6Li foil detector that is appreciably less expensive than available ^3He and BF_3 based detectors and is commercially available. Field comparison with a commercially available ^3He based CRNS showed similar performance. Another detector design based on a plastic scintillometer wrapped with thermal neutron detectors has been demonstrated by Stevanato et al. (2019). All three emerging neutron detection systems can provide additional spectral information about neutron energy that is postulated to be useful in discriminating between vegetative, atmospheric, and soil water, which could improve the usefulness of the CRNS for soil water monitoring.

Abstract

Time-domain reflectometry (TDR) is an electromagnetic (EM) technique using radar principles at radio frequency to estimate water content and electrical conductivity of soil. Buried parallel rods are inserted into soil, with the velocity of the TDR wave affected by the soil water content. In addition, the magnitude of the wave is decreased by electrical losses associated with the bulk electrical conductivity of the soil. From the dielectric properties of the soil, equations allow for the TDR waveform to be converted to water content and electrical conductivity. TDR has been combined with other measurements such as with tensiometers and the cone penetrometer.

Key points

- TDR is a sensor approach to estimate water content and electrical conductivity of soil.
- As a TDR wave propagates through soil, guided by the probe rods, its velocity is decreased by the presence of water.
- Equations to convert from TDR waveform to water content and electrical conductivity are described.
- TDR has become one of the most widely used soil water sensor approaches.

Nomenclature

c	Velocity of light (m s^{-1})
L	Length (m)
t	Time(s)
v	Propagation velocity of electromagnetic waves (m s^{-1})
V	Voltage (volt)
Z_0	Characteristic impedance of probe (ohms)
Z_i	Output impedance of instrument (ohms)
α	Attenuation coefficient
ϵ''_r	Imaginary component of relative dielectric permittivity (relative dielectric loss)
ϵ'_r	Real component of relative dielectric permittivity (dielectric constant)
ϵ_0	Dielectric permittivity of free space (F m^{-1})
ϵ_r	Relative dielectric permittivity (dielectric constant)
ϵ_{ra}	Apparent relative dielectric permittivity (dielectric constant)
θ_v	Volumetric soil water content ($\text{m}^3 \text{m}^{-3}$)
P	Reflection coefficient
σ_0	Electrical conductivity (S m^{-1})
ω	Frequency of signal ($2\pi \text{s}^{-1}$)

Introduction

The vital role of water in maintaining the life of the landscape requires the development of techniques to monitor and sustain water supply and its quality (Clothier and Green, 1997). Time-domain reflectometry (TDR) is an established technology for use in soil and landscape processes, which has become widely used in highly diversified applications (Lekshmi et al., 2014; Binley et al., 2015). TDR offers rapid, in situ, nondestructive measurement of soil water content and ionic solute concentration. This is an electromagnetic (EM) technique using radar principles at radio frequency where estimates of water content and electrical conductivity of soil can be made separately from the same wave (Dowding, 2001). The effect of the soil and water on the propagation velocity of the EM wave is analyzed to provide a reliable measure of the water content. The bulk electrical conductivity (EC) is determined from an analysis of the rate of decrease in amplitude during the propagation of the wave in soil (Topp and Reynolds, 1998). The principles of EM wave propagation are also used for the design of soil probes and to indicate the precision of measurements. The strong interaction between water content and electrical conductivity usually hinders the independent and separate determination of these properties in soil. This difficulty is overcome with TDR where both measurements are from the same sampled region and with the same EM wave.

Water molecules have unique electrical properties that determine the electrical properties of soil (Topp et al., 1980). Because of the strong dependence of soil electrical properties on the amount of water in a soil and on the quality of that water, electrical and electromagnetic measurements can be very useful for characterizing the soil water content. One method with which these properties can be measured is TDR. TDR can be thought of as one-dimensional radar using radio waves that propagate along a wave-guide. This wave-guide is constructed from parallel metal rods that are inserted in the soil. As radio waves travel through any material, the characteristics of the wave are continuously changed by the medium through which the wave is traveling. These changes in wave properties are measured by TDR and a wave equation analysis is used to estimate two electrical parameters of the soil: dielectric permittivity (dielectric constant) and electrical conductivity. These properties are then used to estimate the water content and the electrical conductivity of the soil, respectively (Ferré and Topp, 2000).

As the name implies, time-domain reflectometry relies on the measurement of the travel time of reflected waves. In this way, it is similar to other radar applications. In TDR, the wave velocity is measured by recording the time difference between the entry of a wave into the soil and the return of the reflected wave from the end of the TDR probe. Currently available TDR instruments operate in the range of radio frequencies (10–1000 MHz). In this frequency range, the dependence of the wave velocity on the water content is not strongly influenced by the electrical conductivity of the pore water or the electrical properties of the soil solids. This is supported by direct measurements made since the mid-1970s that show that, while other soil factors such as density, texture, temperature, and soluble salts affect the TDR wave velocity, their effects are less pronounced than are the effects of water content (Lekshmi et al., 2014). That is, the soil water content is the most important soil factor affecting the travel time measured by TDR. This property of TDR makes the method very effective and efficient for the measurement of soil water content.

Soil salinity is an issue of great importance in relation to irrigation and agricultural production in arid and semiarid regions. It has long been realized that the electrical conductivity of pore water can be related to pore-water salinity. However, the bulk soil electrical conductivity is not solely dependent upon the concentration and composition of salts in solution. This property is also highly dependent on the soil texture, the temperature, and the water content. TDR can be used to infer the bulk electrical conductivity of a soil. The energy loss of the transmitted signal is related to the bulk electrical conductivity of the soil. This energy loss is determined from the relative amplitudes of the signal source and that of the wave reflected from the end of the probe. TDR has the advantage of simultaneously measuring both the water content and the bulk electrical conductivity in approximately the same volume of porous medium. Under some conditions, this information can be used to infer the bulk electrical conductivity, and thereby the salinity, of the pore water (Wraith, 2002).

In the 40-plus years since TDR was first applied to soil measurements (Topp et al., 1980), the method has become a de facto standard for soil water content measurement and monitoring (Lekshmi et al., 2014). The popularity of the method for environmental monitoring and research arises from a combination of its accuracy in a wide range of soils and its relative ease of use compared with many other available techniques (Ferré and Topp, 2002). TDR provides real-time, in-situ soil water content measurements. Multiple soil probes can be incorporated into a switching network connected to a single instrument and data logger allowing for remote automated monitoring. For most soils, the accuracy of measurements of volumetric water content change is within $\pm 0.02 \text{ m}^3 \text{ m}^{-3}$ without the need for soil-specific calibration, and similar absolute water contents can be achieved with calibration. There is considerable flexibility in the design and placement of TDR probes, allowing users to modify water content measurement networks to conform to the requirements of any specific study. Finally, because TDR measures the volumetric water content, the data are directly applicable to hydrologic water balance analyses with no need for the measurement of supporting soil parameters such as bulk density.

Measurement of soil water content using TDR

Measuring the volumetric water content of a soil is difficult. As a result, methods have been developed that infer the volumetric water content based on the water potential, bulk electrical conductivity, or dielectric permittivity. The water potential–volumetric water content relationship is nonlinear and hysteretic. The bulk electrical conductivity depends on many factors in addition to the

water content. In contrast, the bulk dielectric permittivity of a soil is highly correlated with the volumetric water content. For these reasons, recent advances in the development of indirect methods of measuring the volumetric water content have focused on methods that rely on the measurement of dielectric permittivity. TDR has long been used as a laboratory method to measure the dielectric Permittivity of liquids. In an unrelated field, TDR has been widely applied to the location of faults in buried cables. However, it was not until it was demonstrated that a single correlation existed between the bulk dielectric permittivity and the volumetric water content for a wide range of porous materials that these two distinct uses came together to give rise to the TDR method for soil water content measurement. Since the 1970s, TDR has been applied at many scales and under a broad range of conditions spanning agricultural and forestry environments and seasonal conditions from summer to winter. In addition, the method has been improved and modified.

Most TDR instruments launch a fast-rise voltage step (rise time < 200 ps) along a transmission line that is connected to a probe that is inserted in the soil or medium of interest (O'Connor and Dowding, 1999). The voltage pulse propagates as a planar EM wave, traveling in the soil and guided by the conductors that form the probe. The properties of the soil that govern the propagation of the TDR pulse are described collectively by the propagation constant of the soil, from which velocity of propagation, v (m s^{-1}), and attenuation coefficient (α) are derived. The TDR instrument records and displays the voltage returning to the instrument as a function of elapsed time following the launch of the voltage pulse. This gives rise to a characteristic plot known as the waveform.

The waveform is a record of the voltage that arrives back at the instrument after being reflected from the end of the probe. Commonly, the returning voltage, V , is displayed as a normalized voltage, known as the reflection coefficient (ρ), as a function of time (t) (Fig. 1, where $V/V_0 = 1 - \rho$), where V_0 is the voltage of the transmitted pulse. From the TDR waveform it is possible to determine both v and α . As discussed above, v is used to infer the volumetric water content while α is used to determine the electrical conductivity. A portion of the TDR step pulse travels a distance, L_{cable} (m), along the connecting cables to the probe and then reflects back to the instrument. A portion of the energy that enters the probe travels an additional distance, L (m), along the probe, and then travels the total distance back to the instrument. Taking the difference in these travel times to be t (s), the velocity of the wave can be determined from the known probe length, L , as:

Fig. 1 Two time-domain reflectometry curves from 20-cm probes in silty clay loam soil. The soils are at similar water content but the soil solution is more conductive in (B), giving a smaller return reflection and resulting lower V_f . In (A) $\theta_v = 0.304 \text{ m}^3 \text{ m}^{-3}$ and $\sigma_0 = 57 \text{ mS m}^{-1}$ and in (B) $\theta_v = 0.271 \text{ m}^3 \text{ m}^{-3}$ and $\sigma_0 = 95 \text{ mS m}^{-1}$.

$$v = \frac{2L}{t} \quad (1)$$

From electromagnetic wave propagation theory, v is given in terms of relative dielectric permittivity and electrical conductivity of soil, which can be expressed as:

$$v = \frac{c}{\sqrt{\epsilon_{ra}}} \quad (2)$$

Where c ($= 3 \times 10^8 \text{ m s}^{-1}$) is the velocity of light and other EM waves in vacuum, and ϵ_{ra} is the apparent relative dielectric permittivity or apparent dielectric constant that controls the rate of propagation of the step pulse. Combining Eqs. (1) and (2) gives:

$$\epsilon_{ra} = \left(\frac{ct}{2L} \right)^2 \quad (3)$$

More complete analyses of the EM wave equations show that ϵ_{ra} is primarily the result of the relative dielectric permittivity (real component) or dielectric constant of the soil, ϵ_r' . Also, ϵ_{ra} is affected to some extent by the electrical conductivity, σ_0 (S m^{-1}), the frequency of the signal, ω ($2\pi \text{ s}^{-1}$), and the relative dielectric loss or imaginary component of relative dielectric permittivity, ϵ_r'' . The effect of these factors on EM waves is expressed as:

$$\epsilon_{ra} = \frac{\epsilon_r'}{2} \left[1 + \sqrt{1 + \left(\frac{\epsilon_r'' + \frac{\sigma_0}{\omega\epsilon_0}}{\epsilon_r'} \right)^2} \right] \quad (4)$$

where ϵ_0 is the dielectric permittivity of free space ($= 8.85 \times 10^{-12} \text{ F m}^{-1}$). Most TDR applications in soil have assumed that $(\epsilon_r'' + \sigma_0/\omega\epsilon_0)/\epsilon_r' \ll 1$, which leads to $\epsilon_{ra} \approx \epsilon_r'$. This assumption allows for the determination of the volumetric water content without prior knowledge of the bulk electrical conductivity.

The high relative dielectric permittivity of water imparts to wet soil a very strong dependence of ϵ_{ra} on the water content. The early laboratory work in TDR adopted an empirical approach, making no assumption about the 'state' of water in porous materials. Instead, it related the TDR-measured ϵ_{ra} to the volumetric soil water content, θ_v ($\text{m}^3 \text{ m}^{-3}$), based on oven drying to 105°C . This early work gave a consistent empirical relationship between relative dielectric permittivity and volumetric water content for a wide range of soils and became a model for calibration of the TDR as a method for measurement of water content. Furthermore, it was found that the relationship is essentially independent of soil bulk density, texture, ambient temperature, and salt content, within the range of these parameters most often encountered. The equation now used widely for calibration is:

$$\theta_v = -5.3 \times 10^{-2} + 2.92 \times 10^{-2} \epsilon_{ra} - 5.5 \times 10^{-4} \epsilon_{ra}^2 \div 4.3 \times 10^{-6} \epsilon_{ra}^3 \quad (5)$$

This relationship has extremely broad applicability, providing good descriptions for the water content of soils of widely varying properties, such as iron-rich volcanic soils, the unfrozen water content in frozen soils, soils with up to 50% gravel, oil shale waste, and crushed concrete. The widely obtained agreement between observations and Eq. (5) has not been true for observations made in low-density soils, mineral soils with high organic or clay contents and artificial soils, such as glass beads. The widespread use of TDR has resulted in a number of applications in which Eq. (5) cannot be used, and some effort has been devoted to finding alternative relationships between ϵ_{ra} and θ_v . However, no relationship has emerged that shows more general applicability without the requirement for other supporting measurements (e.g., clay content, temperature). Various approaches have been presented over the years (e.g. Whalley, 1993; Kojima et al., 2023; Wang et al., 2023).

Alternatives to empirically derived calibrations are often based on dielectric mixing models. The application and use of mixing models require varying levels of prior knowledge about the soil, such as porosity, density, and the relative dielectric permittivity of soil components. The application of mixing models for water content determinations has shown that 'square root' mixing models are most common. Such models are equivalent to a linear relationship between $\sqrt{\epsilon_{ra}}$ and the TDR travel time, t in Eq. (3), which leads to a convenient linear calibration for water content. The linear relationship between θ_v and is supported by calibration data from numerous sources and is very similar to the polynomial expression in Eq. (5) (Fig. 2). Fitting a linear relationship where possible presents a significant improvement over fitting a polynomial calibration curve because there are only two parameters to define, making the fitting procedure much simpler. A linear regression of $\sqrt{\epsilon_{ra}}$ on θ_v gives rise to (Fig. 2):

$$\theta_v = 0.115\sqrt{\epsilon_{ra}} - 0.176 \quad (6)$$

The constant term includes the electrical properties of the dry solids, primarily the bulk density and the relative permittivity of the constituent material. The slope coefficient in the first term on the right-hand side embodies the effects of dissolved solutes and clay surfaces on the electrical properties of the water phase as seen by TDR. This slope changes relatively slowly as salt and clay contents increase. Clay and salt content do introduce some curvature to the relationship between $\sqrt{\epsilon_{ra}}$ and θ_v , indicating the importance of calibration checks to assure an appropriate calibration for high-resolution measurements and for unique soil conditions. Precise calibration equations become more important where absolute measures of water content are required as contrasted with differences or changes in water where more general calibrations usually suffice.

Fig. 2 The similarity between Eq. (5) (dashed line) and Eq. (6) (solid line) over the water content range ($0.05\text{--}0.45\text{ m}^3\text{ m}^{-3}$) applicable for most soils. Note the x-axis is $\sqrt{\epsilon_{ra}}$ and shows the linearity of Eq. (6) (White et al., 1994).

Instrumentation and wave-guides

The original and still widely used TDR instrument for soil was the portable cable-tester. This instrument displays the TDR waveform on a screen, allowing analyses to be performed and recorded manually (Lekshmi et al., 2014). Alternatively, the data can be recorded and analyzed digitally on a personal computer (PC). Currently, a number of companies offer TDR instrumentation aimed directly at soil and environment studies. These offer automated analysis of the TDR waveform as a part of the basic instrument with network switching for multiple probes as an option. Most of these instruments make use of general calibration relationships that closely approximate Eqs. (5) and (6). In addition, they allow for the calibration relationships to be customized for the desired soil characteristics.

One of the most important components of a TDR system is the soil probe or transmission line. The basic elements are the conductive components, often parallel metallic rods, which act as wave-guides. Currently the most common soil probes are of the parallel rod type, consisting of two or three parallel rods. These may vary in length from $0.1\text{--}1.0\text{ m}$ and with probe separations from $0.01\text{--}0.1\text{ m}$. Probes that use bare metallic rods measure total water content along the path of the TDR pulse regardless of the distribution of water along this path. However, the distribution of electromagnetic energy is not uniform in the directions perpendicular to the rods. Furthermore, the distribution of energy depends on the number of rods, their diameters, and their separations. A rod separation to rod diameter ratio less than 10 is a practical rule of thumb for probe design. Further, the rod diameter should be large in relation to the dominant pore size, e.g., 10 times the dominant particle or aggregate size. We have found that 6-mm rods spaced at 50 mm have worked well in a variety of studies in tilled and untilled agricultural soil.

Many other probe configurations have come into current use, including profiling probes with the conductors mounted on opposite sides of a dielectric central core. The parallel wires mounted on a central core have been diversified to include a helical-wrapped pair on a single shaft probe and serpentine pathways on a plastic surface giving a surface probe. In all cases the energy density of the propagating wave decreases rapidly with distance from the conductors. Spatial weighting of the measurements in the cross-section perpendicular to the direction of wave propagation is a very important consideration, especially for probes that have nonmetallic components near the metal rods. Numerical analyses have been applied to the wave-equation response from parallel rod probes embedded in a porous medium. One aspect of this work was the definition of sample areas in the transverse plane that are not limited to predefined shapes, allowing for a more realistic description of the lateral sensitivity of different probe configurations. In general, TDR probes should be installed in a manner that minimizes variability of the water content within their sampling volume, especially in the direction that is transverse to the rods.

An important application of TDR relates to the measurement of shallow soil water content profiles. Three general approaches to water content profiling are depicted in Fig. 3 using vertical and horizontal probes. In general, vertical rods (Fig. 3A) give the most

Fig. 3 Three options for measurement of water content profiles. (A) Adjacent vertical; (B) horizontal; (C) segmented vertical. Probe lengths and intervals can be adjusted to the monitoring requirements. Installing probes in (A) and (C) off vertical results in a compromise between vertical and horizontal installation but optimizes the advantages from each (Ferré and Topp, 2002).

accurate measurement of cumulative water from the surface to the ends of the rods, regardless of the water content distribution with depth. Horizontal rods (Fig. 3B) give higher resolution of the water content profile, with less accurate measurements of the total water stored to a given depth. It is possible to place probes depicted in Fig. 3A and C at an angle off the vertical. Angled rods at say 45 degrees give an optimal compromise between horizontal and vertical configurations. Another consideration is the potential for causing cracks in the soil or gaps around the rods. These features can have a significant impact on TDR measurements and on water movement, and vertical emplacements are most susceptible to these influences. In addition, water content profiles that are determined by the differencing of adjacent measurements (e.g., Fig. 3A) introduce the error from both measurements, which can lead to a cumulative error as large as $\pm 0.03 \text{ m}^3 \text{ m}^{-3}$. On the other hand, horizontal rods require excavation for insertion at depth, which can also affect water movement. In addition, because the head of a horizontal probe is placed beneath the ground surface, it is important that it be watertight to avoid the influence of water entry. Practically, vertical rods are the simplest to install. However, their tendency to move vertically out of the soil during winter by the processes of frost-heave can be countered somewhat by the use of angled rods.

An alternative to the continuous-rod probes is the segmented probe depicted in Fig. 3C. This probe configuration makes use of diode-shortening to achieve probe segmentation electronically and is available commercially. This probe is essentially a series of vertical probes placed in the same hole. As a result of its design, these probes provide both the water content profile and the total profile stored water from a single installation. Installation of this type of probe is of critical importance as any disturbance of the soil adjacent to the probe is in the most sensitive part of the measured region. Similarly, air gaps or preferential water flow along the probe will also affect measurements.

Impact of salinity on water content measurement

The explicit effect of the bulk electrical conductivity on TDR water content determinations has not been fully evaluated. Research is continuing with varied EM techniques to define conditions when the direct effect of bulk electrical conductivity (EC) results in unacceptable error in water content estimates. It appears, however, that the influence is very small for mineral soils having a clay content less than 50% and pore-water electrical conductivities less than 5 dS m^{-1} . For example, measurements in a soil of 55% clay gave an overestimate of water content of $0.014 \text{ m}^3 \text{ m}^{-3}$ due to the assumption that $\epsilon_{ra} = \epsilon_r'$. Typically, high EC conditions lead to difficulty in measuring the water content due to total extinction of the waveform through energy loss. This places a practical limit on the maximum length of TDR rods. However, to maintain acceptable water content accuracy, probe length should be at least 7.5 cm. If the EC is too high to use probes at least 7.5 cm in length, nonconductive rod coatings can be used to minimize the effects of signal loss. These coatings change the water content calibration and they should only be used when absolutely necessary.

Some of the limitations of TDR analysis and application may be addressed by a new approach to TDR waveform analysis. Standard analyses involve interpretation of the time of arrival of reflections. However, in addition to this time-based analysis, a TDR waveform can be analyzed in the frequency domain using Fourier analysis. Conversion of TDR data into the frequency domain provides additional frequency-dependent information about the electrical properties of the soil and water. Frequency domain analyses of measurements made with 3-cm length probes may provide high-precision measurement of relative dielectric permittivity in saline soils where the time-domain analysis is not feasible. Further developments of this approach may extend the range of applicability of TDR.

Measurement of bulk electrical conductivity using TDR

As the TDR wave propagates through soil guided by the probe rods, its velocity is decreased by the presence of water. In addition, the magnitude of the wave is decreased by electrical losses associated with the bulk electrical conductivity of the soil, σ_0 . The decrease in magnitude of the wave is expressed in the attenuation coefficient, α . It is possible to express σ_0 in terms of the values obtained from the TDR waveform (Fig. 1):

$$\sigma_0 = \left(\frac{1}{120\pi L} \right) \left(\frac{Z_0}{Z_i} \right) \left(\frac{2V_0}{V_f} - 1 \right) \quad (7)$$

where Z_0 (ohms) is the characteristic impedance of the TDR probe (a factor of the probe geometry), Z_i is the output impedance of the TDR instrument, V_0 (volts) is the initial step voltage output and V_f is the final voltage remaining after all multiple reflections from the probe, respectively. In practice, the quantity $(Z_0/120\pi L Z_i)$ is often treated as a calibration constant for the instrument, cable, and probe combination, which can be obtained from measurements in solutions of known EC. After the probe and TDR instrument have been characterized, the bulk EC is calculated from the value of V_f as the only independent variable at each measurement site or measurement time. Although the measurement is straightforward, it is important that V_f be determined well after all multiple reflections have returned and the TDR waveform has reached a final constant value.

The bulk EC measured by TDR has applications in research into solute transfer processes, particularly ionic solute breakthrough experiments. At a heterogeneous field site, using vertically installed TDR rods, solute mass flux measured with TDR was in good agreement with that obtained from solution samplers. The TDR-measured EC has been used to monitor nitrate levels in the field with a view to improving crop nutrient management and minimizing leaching to groundwater.

Impact of water content on pore-water salinity measurement

The EC of the soil solution is often desired for soil and environment studies, particularly in relation to soil salinity assessment or monitoring migration of polluting chemicals. The relationship between bulk EC and solution EC is strongly dependent on both the soil water content and the clay content of the soil. TDR offers the distinct advantage of measuring both water content and EC in the same sample and under identical conditions. Thus, TDR can be very useful for establishing both the water content and the pore-water EC simultaneously. TDR has been used in both direct and indirect approaches and to elucidate the relationship among water content, bulk EC, and solute EC. However, it is not always possible to determine the pore water EC if the water content varies along the TDR probes, as this will give a gradient of pore water EC along the probe.

Conclusion

Since the early applications in soils, TDR has revolutionized the field measurement of soil water content. In 1991, a survey of soil physicists in four countries reported TDR was used one-third as often as gravimetric sampling and one-half as often as neutron moderation. It is most likely that TDR use had surpassed both these methods by the end of the 1990s, making it more ubiquitous than any other technique. The capability to log TDR data and the relatively nondestructive nature of the installations have allowed in situ monitoring, contributing to the much wider use of TDR. For water balance and water-use efficiency studies, TDR is particularly applicable because the probe designs and orientations can be chosen to meet a variety of conditions, such as agricultural row crops, drip irrigation patterns, and forested landscapes. Through the application of TDR in soil much has been learned about the soil's electromagnetic properties in the radio frequency range. This knowledge has assisted in the development of other electromagnetic techniques, such as ground-penetrating radar and remote sensing using either active or passive microwave radars. TDR is specifically valuable for 'ground-truthing' radar applications because both are interpreting measured EM properties of soil. As a consequence, TDR can be applied to defining the sampling regions of radar applications by appropriate choice of probe geometries for the TDR. Water content measurement by capacitance techniques has been accelerated recently, in part because appropriate frequencies and probe geometries were identified through TDR studies. Although capacitance devices are less expensive, they have not yet offered the ability to measure EC as can be done by TDR.

TDR is prominent among several emerging technologies being used to enable the long-neglected investigation of roots as the major agents of water and chemical transfer in soil. TDR water content measurements also improve the value and significance of other environmental parameters. For example, frequent measurements of temperature, water content by TDR, and oxygen concentrations in the rooting zone of maize can help to demonstrate when tillage and trafficking limit both O_2 supply and crop growth. Prior to TDR, measurements of O_2 supply for roots and other biota in the soil had not been possible. Time-domain transmissiometry (TDT), which is similar to TDR, has been combined with a soil penetrometer to measure both soil strength (compaction) and water content. The combination of sensors greatly enhances the value of the soil penetrometer as a diagnostic tool for soil compaction.

Regulations now play a leading role in the need to monitor soil contamination and harmful infiltration of contaminated solutions into groundwater. Cities in the USA such as Los Angeles, Tucson, Las Vegas, and Glendale are using TDR for such

monitoring. Agencies from around the world have reported using TDR in environmental monitoring applications as diverse as nonaqueous liquid-phase concentrations (Sweden), subsurface pollutant detection (United Arab Emirates), changes in groundwater level and crude oil thickness (USA), characterization of diesel-contaminated soil (Canada), and measuring water-table elevations within sidewalk systems (USA).

The application of TDR in soil is continuing to develop and diversify in ways that will enhance the value of TDR for soil and environmental monitoring. The analyses of spatial sensitivity within probes have facilitated designs for specific uses, often allowing combinations of TDR with other measurements such as with tensiometers and the cone penetrometer.

Abstract

Traditional methods to assess soil properties or monitor soil processes typically rely on point data. They often fail to represent the heterogeneity of soil. Airborne remote sensing techniques allowed us to measure proxies for soil properties or variables at regional scale, but often covering only the first few centimeters of soil. Ground-based geophysical methods can fill in the gap between these two scales. They primarily observe variations in the thermal, electrical, magnetic, electromagnetic or seismic properties of the subsurface to map its characteristics or to monitor dynamic changes and can yield 2- or 3-D quantitative information on soil properties or processes. Geophysical methods have been applied in various soil-related research fields: from soil mapping and precision agriculture, to geotechnical engineering and soil remediation and to archeology and forensic investigation. This chapter briefly introduces the ground-based geophysical techniques appropriate for soil applications.

Key points

- Geophysical methods are key to bridge the gap between point measurements and remote sensing techniques for soil applications.
- This chapter introduces the ground-based geophysical techniques relevant for soil applications, commonly used equipment and limitations of each technique
- The use of geophysical techniques for soil applications ranges from soil mapping and precision agriculture, through geotechnical engineering and soil remediation, to archeology and forensic investigation.
- We discuss critical data processing steps such as inversion and pedophysical relationships.

Introduction

The soil plays a crucial role in the redistribution of energy, water and solutes in terrestrial systems. Relevant scales range from the single pore and the soil-root interface, through the field scale, to encompass the entire globe. The multi-scale heterogeneity of soils presents a challenge to the representation of processes over different scales and to the parameterization of corresponding models. Traditional observation methods for soil processes often rely on (a network of) point data from manual sampling or sensors that capture states and attributes of soil system functioning. These point data often fail to capture the heterogeneity of soil properties at larger scale. Over recent decades, airborne remote sensing techniques (from drones to satellites) generated proxies for near-surface soil properties at the regional scale (e.g. SMOS, SMAP, Sentinel-1, Sentinel-2 campaigns). Nevertheless, those methods only interrogate the first few centimeters of the soil. In addition, the time-intervals between measurements and spatial resolution are rather coarse (days and 10–100 s of meters, respectively). Ground-based geophysical methods can fill in the gap between local point measurements and remote sensing products. Geophysical methods typically observe variations in the thermal, electrical, magnetic, electromagnetic or seismic properties of the subsurface to map its characteristics or to monitor dynamic changes. They can yield 2- or 3-D information on soil properties (e.g., texture or organic matter content) or state variables of interest (e.g., temperature, soil moisture, salinity) at centimeter or decimeter resolution.

This chapter briefly introduces key ground-based geophysical techniques relevant for soil applications, commonly used equipment and limitations of each technique. The use of unmanned aerial vehicles (UAVs) for geophysical surveys (e.g. EMI, GPR, magnetometry) or sensors mounted on towers (e.g. L-band radiometry, cosmic-ray neutron sensing) are not covered here, but is certainly also relevant for soil applications. Airborne GPR and EM are increasingly being used on UAVs.

Geophysical variables and pedo- or petrophysical models

For a geophysical measurement, we register the response of the soil to a signal which is naturally present (e.g. gravity) or which is actively introduced by the observer (e.g. an electrical current). For soil applications, electromagnetic energy is most used, alongside acoustic waves and gravitational fields. In all cases, the observed change in voltage in the measurement device is related to the geophysical response. The most straightforward example of this process is the direct current (DC) resistivity method, whereby a current I is introduced into the soil, after which the resultant potential difference (or voltage V) between pairs of electrodes is recorded with a voltmeter. The resistance of the recorded volume is then obtained through Ohm's law. To translate the collection of signals (e.g. resistances) to a distribution of the geophysical property (e.g. the electrical resistivity distribution of the bulk soil), we then have to incorporate information on the measurement geometry, the physical processes taking place during the measurement and the nature of the soil in a process called 'inversion.'

Typically, the inferred geophysical properties are not the primary property of interest, but they are used as a proxy for a soil characteristic or state variable. Therefore, relationships are established between these properties of interest and the geophysical properties. Such relationships are called petrophysical or, in the field of soil science, pedophysical relationships. A pedophysical relationship expresses the influence of different soil properties and state variables on the geophysical property. Soil electrical resistivity is for example affected by, among others, pore water salinity, soil texture, porosity, temperature and soil moisture. Therefore, several sources of independent data or calibration data are necessary to develop pedophysical relationships. We give an overview of the geophysical methods, the properties measured and examples of the derived properties and states in [Table 1](#).

Applications of geophysical methods in soil science

During the past decade geophysical measurement and data processing techniques became more affordable and easier to deploy. As such, these instruments offered the potential to explore and monitor the spatio-temporal dynamics of soil. In their review on hydrogeophysics, [Binley et al. \(2015\)](#) pointed out the expanding range of applications: from ecosystem science and biogeochemistry to agronomy and soil mapping. Since then, the possibilities have only expanded. Civil and geotechnical engineering problems are increasingly addressed using geophysics, especially when the application is water-related. For example, ERT, GPR, and self-potential (SP), combined with high-precision leveling, are used to assess sinkhole risks and several authors have used ERT to monitor landslide activity. Another common application is soil pollution and remediation monitoring in polluted sites. The efficiency of geophysical techniques for soil remediation monitoring greatly depends on the nature of the pollution and how it results in specific electrical or magnetic signatures. Geophysical methods have become ubiquitous in archaeological practice and heritage management. The first applications started in the 1950s and 1960s. Magnetometry instruments are the workhorse for archaeological prospecting, complemented with ground penetrating radar, direct-current resistivity and electromagnetic induction surveys. Archeological applications have also driven the deployment of geophysical instrument (arrays) geared at high sensitivity and sampling density. Geophysics is also used for forensic investigations. For example, [Doro et al. \(2022\)](#) used ERT to locate clandestine graves and monitor human decay within the subsurface.

Precision agriculture is one of the fastest growing soil-centered areas for adopting geophysical methods. Where EMI has been used for years as a qualitative soil mapping tool or for more detailed experimental design, multi-geometry devices now allow for

Table 1 Geophysical methods, their properties measured and examples of derived properties and states.

<i>Geophysical Method</i>	<i>Common abbreviations</i>	<i>Geophysical Properties</i>	<i>Examples of Derived Properties and States</i>
Electrical resistivity tomography	ERT, ERI	Electrical conductivity	Water content, clay content, pore water conductivity
Induced polarization	IP, EIT	Electrical conductivity, chargeability	Water content, clay content, pore water conductivity, surface area, permeability
Spectral induced polarization	SIP	As above but with frequency dependence	Water content, clay content, pore water conductivity, surface area, permeability, geochemical transformations
Self-potential	SP	Electrical sources, electrical conductivity	Water flux, permeability
Electromagnetic induction	EMI, FDEM, TDEM	Electrical conductivity	Water content, clay content, salinity
Magnetometry	MAG	Magnetic susceptibility	Ferromagnetic iron oxide content, redox conditions
		Magnetic susceptibility, Remanent magnetization	Ferromagnetic iron oxide content, redox conditions.
Ground penetrating radar	GPR	Permittivity	Water content, porosity, stratigraphy
Seismic		Elastic moduli and bulk density	Lithology, ice content, cementation state, pore fluid substitution
Seismoelectrics		Electrical current density	Water content, permeability
Nuclear magnetic resonance	NMR	Proton density	Water content, permeability
Gravity		Bulk density	Water content, porosity
Distributed temperature sensing	DTS	Temperature	Water content, thermal properties (conductivity and diffusivity)

ISSN 0043-1397. <https://doi.org/10.1002/2015wr017016>.

inversion of the apparent electrical conductivity, unlocking information of vertical heterogeneity in addition to horizontal patterns. Combination with machine learning techniques has resulted in new possibilities. RomeroRuiz et al. (2021) used seismic to locate areas suffering from chronic soil compaction. GPR has been used at several sites to locate tile drainage components. Also, the monitoring potential of EMI and ERT and its relationship with soil moisture has been extensively used. Several researchers use geoelectrical methods to study the root water uptake of trees and crops and estimate the efficiency of applied irrigation patterns. This has led to the application of EMI, and also ERT, in plant phenotyping through the assessment of soil moisture depletion.

Previously, the phenotyping community struggled to incorporate environmental effects into its studies in field environments, especially for the below-ground part of the plant. Geophysics offers a window into that ‘hidden half.’ Fig. 1 gives an overview of the field setup of different geophysical techniques covered in the chapter.

Electrical resistivity tomography (ERT)

Electrical Resistivity Tomography (ERT) is a technique, which infers the bulk electrical resistivity of the soil between electrodes. The bulk electrical resistivity corresponds to the combined resistivity of soil particles, pore water and air. A basic measurement system consists of four electrodes (A, B, M, N), a transmitting electrode pair and a receiving electrode pair. The transmitter electrode pair applies a quasi-direct current (I) to the ground using rectangular DC current pulses or an AC current at low frequency to avoid polarization of injection electrodes A and B. The receiver measures the voltage (V) between the potential electrodes M and N (see Fig. 2). Resistivity meters then register a resistance (R) for each combination of four electrodes, based on Ohm’s law $R = V/I$. For a tomography, many different combinations of current and potential electrodes are used for injection and measurement. The electrodes can be inserted into the soil surface or at several depths as borehole electrodes or a combination of both.

From the current, the voltage and a geometric configuration factor (k), the apparent electrical resistivity (ρ_a) is calculated. The geometric factor depends on the spatial arrangement of the four electrodes and the geometry of the measurement area (e.g. presence of topography). Resistance is an extrinsic property (i.e., depends on the way it is measured), whereas resistivity is an intrinsic property (i.e., depends only on the material in which the measurement is performed). We call the obtained resistivity “apparent”, because it represents the resistivity of a hypothetical, homogeneous medium, which would give the same resistance value for the applied electrode arrangement. The measured, apparent resistivity is a complex average of the resistivities of the various materials that the current encounters.

A soil-specific pedophysical relationship is necessary to derive any soil state variable or property from electrical resistivity measurements. A well-known electrical resistivity model is the empirical Waxman and Smits (1968) model that extends Archie’s Law to account for surface conduction. Apparent resistivity is also affected by temperature. Ma et al. (2010) gives an overview of temperature correction models.

Fig. 1 Overview of the field setup for the different geophysical techniques for soil applications covered in this chapter.

Challenges and limitations

At the core of geoelectrical methods for application to soil is the assumption that the electrical conductivity map obtained of the subsurface can be translated into soil properties or state-variables via site-specific pedo-electrical relations calibrated with laboratory or field data. Common practice assumes spatially homogeneous relations, which neglects the impact of soil heterogeneity on those relations. This can cause significant errors in translating the electrical measurements to the hydraulic state variables. Standardized approaches to establish and upscale pedophysical relationships are, therefore, crucial to increase the accuracy of the method. Furthermore, the inversion remains a source of uncertainty, since an infinite number of electrical conductivity models fit the noisy geoelectrical data equally well.

Fig. 2 Basic concept of electrical resistivity measurement of the subsurface.

Fig. 3 Diagram of the FDEM working principle, indicating the primary (H_p) and secondary (H_s) magnetic fields.

Electromagnetic induction (EMI)

EMI uses low-frequency electromagnetic fields to investigate electrical and magnetic properties of the subsurface. For most soil applications, EMI measurements are performed in the frequency domain and described as frequency domain electromagnetics (FDEM). This means that the analysis of the signal is done with respect to frequency, rather than time. A magnetic field oscillating at a frequency between 1 and 100 kHz is generated by passing an alternating current through a transmitter coil (Tx, see Fig. 3) that consists of a small wire loop. This primary field (H_p) induces eddy currents¹ in conductive parts of the soil, which in turn generate a secondary magnetic field (H_s) that induces an oscillating current in the receiver coil (Rx). The size and shape of the subsurface volume that influences the observed current depends on the separation and respective orientation of transmitter versus receiver coil. For soil applications, coils are generally horizontally or vertically coplanar, or in a perpendicular orientation. One or more transmitter-receiver pairs are fixed in a rigid boom (so-called fixed-loop systems) with coil separations ranging from 0.20 m to 6.00 m. Although multi-frequency instruments are available, fixed-loop instruments used for soil applications operate at a single operating frequency, but integrate multiple transmitter-receiver pairs to enable geometrical depth sounding.

Evaluating the ratio of the secondary (H_s) to the primary magnetic field (H_p) at the receiver when both fields are out-of-phase or in-phase allows electromagnetic properties of the investigated volume to be derived. In low-conductive environments, the out-of-phase response is quasi-linearly related to the subsurface apparent conductivity. This approximate, but straightforward, relationship, is only valid under certain conditions, requiring a sufficiently small Tx-Rx distance, operating frequency and subsurface conductivity (Callegary et al., 2007). It is typically referred to as the low induction number approximation (LIN). Some instruments use multiple frequencies for different Tx-Rx distances to remain under this condition. When this condition is not met, e.g., in saline

¹Eddy currents (also called Foucault's currents) are loops of electrical current induced within conductors by a changing magnetic field in the conductor according to Faraday's law of induction.

environments, the relationship becomes more complex and a full evaluation of Maxwell's equations is needed to obtain reliable apparent conductivity values (Hanssens et al., 2019). Commercially available instruments developed for soil applications usually output the out-of-phase response as apparent electrical conductivity (σ_a) using the LIN approximation. Hence, they underestimate subsurface apparent electrical conductivity at higher conductivities and do not always offer access to the raw data.

In low-conductive environments (ca. <100 mS/m) the in-phase response informs on changes in soil magnetic susceptibility (κ). Although not widely used, current instrumentation allows reliable large-area mapping of soil susceptibility alongside apparent conductivity. Relating the in-phase response to quantitative changes in subsurface magnetic susceptibility can be ambiguous due to complex spatial sensitivities and the influence of conductivity on this component. Nevertheless, recent advances show the potential of soil magnetic susceptibility modelling (Klose et al., 2018; Delefortrie et al., 2018).

Challenges and limitations

Although current FDEM instruments are increasingly well-calibrated, issues of absolute and relative signal calibration burden data interpretation. Offsets from absolute zero, i.e., resulting in a non-zero response when making air readings, mainly exacerbate quantitative interpretation of the in-phase response, while, particularly under the influence of temperature variations, drift with time introduces errors in all signal components. Accounting for these issues is required to allow reliable quantitative data interpretation. To this end, adaptive calibration (Thiesson et al., 2014) and drift correction protocols (Delefortrie et al., 2014) are available. Resolving these issues can aid exploiting the full potential of inversion methods geared toward 3D models of soil conductivity and magnetic susceptibility.

Magnetometry and magnetic soil mapping

Magnetometry is a passive method that measures ambient magnetic fields. The interplay between Earth's magnetic field and magnetic materials in the subsurface lies at the heart of magnetometric prospecting. Magnetic materials can be considered as magnetic dipoles that are magnetized by the influence of Earth's magnetic field (see Fig. 4). In addition, those materials can possess a residual magnetization (remenance), which persists after an external magnetic field is removed and remains independent of weak magnetic fields. This is common in anthropogenic materials, such as iron objects or clay bricks, that obtain remanence through the production process. At any location, the resulting total magnetic field can be measured and described by its intensity, and its directional components. Crucial in magnetometer surveying is accounting for the influence of diurnal variations in Earth's magnetic field intensity, which are in the same order of magnitude of soil magnetic variations as natural and anthropogenic processes. To remediate this, stationary magnetometer measurements are conducted alongside roving measurements and subtracted from the survey data. Alternatively, magnetometers can be used in gradiometer mode, whereby two magnetometers are positioned at a fixed distance along the same axis. In such a configuration, the difference between the observations from both sensors is taken to remove diurnal variations, and provide more detailed insight into soil variations.

Two main types of magnetometers are in use: (i) total field magnetometers measuring the total magnetic field intensity and providing a scalar measurement (e.g., alkali-vapor (mainly cesium-vapor) magnetometers), and (ii) magnetometers recording a vector component (e.g., fluxgate instruments). The latter type is often configured in gradiometer mode as standard, i.e., as fluxgate gradiometers. More detailed discussions of the principles of magnetometry can be found in Everett (2013). Apart from dominating the use of geophysical methods in archaeology, and use in unexploded ordnance detection, magnetometry is rarely deployed in soil applications. Pilot studies, however, have shown that even the weakly magnetic signal rendered by iron oxides in soils can be used to detect influence of soil tillage (Mathé and Lévêque, 2003), whereas clay brick drainage pipes are straightforward magnetic targets due to their strong magnetic remanence (Rogers et al., 2006).

Alongside magnetometry, other methods enable magnetic soil mapping by targeting the induced magnetization, or magnetic susceptibility, directly. Complementing the potential of FDEM instruments, dedicated susceptibility meters (e.g., the Bartington MS2) are used to map the magnetic signal of topsoils in pollution (e.g., Declercq et al. (2019)) or ecological studies (e.g., Grimley

Fig. 4 Diagram of the working principle of a magnetometer showing various instrument configurations (vertical gradiometer, whereby observations of the upper sensor are subtracted from those from the bottom sensor) and inclusion of a stationary base station for recording diurnal geomagnetic variations).

et al. (2008)). Such instruments, consisting of inductor-capacitor circuits operating through principles of electromagnetic induction, only offer small depths of investigation that are limited to the upper centimeters below the surface. Downhole logging configurations, however, can be deployed to gain better insight into vertical magnetic variations.

Challenges and limitations

The inherent relationship between the soil magnetic signal and its mineralogical composition, as well as its independence from short-term moisture dynamics, presents good opportunities for soil applications. Broadly described, the soil magnetic signal is influenced by pedogenic processes (such as weathering, reduction and oxidation of iron-bearing minerals) and anthropogenic processes (e.g., the heating of soil or the input of detrital materials such as magnetic particulate matter), which both primarily occur in the upper soil layer, as well as the lithology of the parent material (e.g., weathering of igneous bedrock). A comprehensive overview discussion on pathways to soil magnetism is provided by Jordanova (2017).

Magnetometer surveys have potential to study soil erosion (Jordanova et al., 2014), redox variations (Grimley et al., 2008), or as an indicator for the spatial distribution of soil nutrients (Miroshnychenko et al., 2021). Here, combined use of adaptive instrumentation, for instance FDEM instruments operating at different frequencies, or the joint deployment and inversion of FDEM and magnetometry instrumentation can provide a more robust basis for field applications of magnetic soil mapping. Nevertheless, more work is needed to consolidate the fundamental framework for relating magnetic observations to investigated aspects of soil functioning across different soil types (Jordanova, 2017).

Ground penetrating radar (GPR)

Ground penetrating radar (GPR) uses electromagnetic fields in the mega-to-gigahertz (MHz - GHz) range to characterize the soil. Compared to EMI, these higher frequencies put GPR in the propagation regime, whereby the emitted fields behave as waves that propagate, reflect and refract in the media they travel through. Acquisition of GPR data can be done very rapidly (see Fig. 1) and, due to its wave-based nature, this method provides a much higher vertical (depending on soil properties and the source frequency) and horizontal resolution than other geophysical methods (e.g., ERT or EMI). For this reason, the GPR method is one of the most widely used geophysical methods in soil sciences and near surface surveying. GPR instruments are composed of a transmitting (Tx) and a receiving (Rx) antenna (see Fig. 5). The former sends an electromagnetic wave into ground, after which the receiver records the reflections of the emitted wave as it travels through the soil. The velocity of the wave is determined by the soil dielectric permittivity (ϵ). When the electromagnetic wave encounters a change in permittivity, part of the energy of the wave is reflected on the interface, while the remaining energy is transmitted or refracted. Recording these reflections at the receiver provides information on the structure of the subsurface (Fig. 5). These reflections are recorded in function of time, resulting in a so-called GPR-trace at each measurement location, traces can be aggregated in transects (radargram) or 3D volume. Several processing steps are needed to allow reliable interpretation of GPR data: the removal of interfering frequencies (e.g., background removal and 'dewow'), converting wave traveltimes to depth (velocity analysis and migration) and adjusting signal gain (to compensate, for instance, for energy loss with depth). An overview of standard GPR processing steps is given by Cassidy (2009).

The dielectric permittivity can be linked to other soil characteristics such as soil moisture content. This relationship has been widely used for Time-Domain Reflectometry (TDR) soil moisture sensors. Similarly, GPR has been used to map soil moisture by measuring the direct (not reflected) wave (Fig. 5) that travels along the ground surface or using air-launched methods. However, these methods usually only assess the soil moisture of the upper layer (few centimeters). Transmission GPR can also be used to measure larger volume by using the wave speeds between boreholes. Huisman et al. (2003) provided a review of the use of GPR for soil moisture estimation. GPR can also be used to locate the depth of soil horizons with different soil texture and associated water retention properties (thus producing abrupt vertical changes in water content) (André et al., 2012). In water-saturated conditions, GPR methods may help in locating zones with different porosities (i.e., different water content) or fractures, both associated with zones of increased permeability. Due to its simplicity, the empirical Topp's equation is typically used to relate the dielectric permittivity with water content and vice-versa. Yet, other physics-based models between the soil bulk ϵ and the dielectric properties

Fig. 5 Diagram of the GPR working principle. On the right, a GPR trace is shown as would be obtained from the received reflections shown in the diagram.

of soil individual constituents exist and are often based on volume averaging (Roth et al., 1990). Such models are successful in providing information about soil texture, soil structure or even help monitoring ice content in the soil.

The primary use of GPR for soil applications, however, is mapping out the individual traces along profiles and volumes recorded with a fixed transmitter-receiver distance. In these so-called reflection surveys, the location and extent of interfaces between materials with different permittivities are identified by visualizing their recorded reflections in GPR traces across surveyed areas. Hereby, one key advantage of GPR is the potential for the 3D discrimination of small subsurface permittivity discontinuities. Alongside use for environmental applications (Knight, 2001), this potential is particularly exploited in archaeology where the ability for identifying anthropogenic (e.g. Verdonck et al. (2020)) and palaeoenvironmental (e.g. Chapman et al. (2009)) phenomena of GPR is unparalleled.

Challenges and limitations

Despite its unique advantages in subsurface exploration, a key limitation in GPR surveying is energy loss of the travelling radar wave, leading to decreasing signal-to-noise ratios. This energy loss increases with travel distance in the propagation direction, attenuation and the amount of reflected and scattered energy (Annan, 2009). With higher conductivity (for instance due to high clay content or salinity), attenuation will rise, resulting in a limited depth of investigation or impeding use of GPR altogether. Attenuation has a stronger influence on high frequency waves. While lower frequency waves are more resilient to such dampening, these offer only limited spatial resolution (Annan, 2009). The choice of a GPR survey's central frequency therefore implies a trade-off between resolution and depth of investigation that takes into account the expected conductivity of the study area. In soil with high stone content, the energy loss due to signal scattering can also decrease the depth of investigation. Generally, GPR methods perform better in partially water-saturated soils with textures containing low or moderate clay contents. Despite these limitations, the GPR methods will continue to be one of the most widely used geophysical methods in soil science due to the unmatched sensitivity of ϵ to water content changes, their versatility and the relatively well-developed set of tools for interpretation of GPR signals.

Induced polarization (IP)

Polarization represents the ability of a soil to store and release electrical charges. Induced Polarization (IP) measurements can be conducted in the time-domain (Time Domain Induced Polarization or TDIP) or in the frequency-domain (Frequency Domain Induced Polarization or FDIP). When deployed in the field, the layout used is the same as for conventional electrical resistivity measurements. In the time-domain, the voltage at the receiver electrodes is not only measured during direct current injection, but also after the current has been switched off. The voltage decay is not instantaneous, but rather exhibits a gradual decrease that reflects polarization mechanisms. A common way to quantify the polarization is to integrate the voltage decay as shown in Fig. 6A. This

Fig. 6 Induced polarization measurements in the time-domain and in the frequency-domain.

results in an apparent chargeability usually expressed in mV/V. In the frequency-domain, an alternating current is applied and the relative phase-shifted voltage is measured. Data collected consists of a magnitude (i.e., transfer resistances, R) and a phase shift between the applied current and the measured voltage (Fig. 6B). When phase and magnitude are recorded over a frequency range from 10^{-3} Hz to several kHz, this is generally referred to as Spectral Induced Polarization (SIP). More information about IP methods is available in Kemna et al. (2012).

In the low frequency range (below 1 MHz), four main mechanisms explain the polarization occurring in porous media: (i) electric double layer polarization occurring in the layers surrounding mineral grains and depending on the nature of the grains; (ii) membrane polarization varying with the grain or pore size distribution, (iii) electrode polarization occurring in the presence of conductive minerals and (iv) the Maxwell-Wagner polarization (generally observed for frequencies >1 kHz) that occurs in multiphase systems when changes in dielectric permittivity and conductivity exist between the different phases. In contrast to ERT, IP allows electrolytic conduction to be distinguished from surface conduction. This is of great interest as soils often have significant surface conductivity.

Challenges and limitations

Polarization depends on numerous parameters such as the type and amount of conductive minerals, the presence of clay minerals, the pore fluid composition, the pore saturation, the presence of insoluble hydrocarbons, the size and shape of the pore space, the size and shape of the grains or the temperature, just like resistivity. While this can be seen as a strength of the IP method, it can also complicate the interpretation of data as these parameters can vary simultaneously. Compared with resistivity, however, the link between the physico-chemical mechanisms described above and the IP response observed in the field or in the laboratory is not yet fully understood. Finally, collecting reliable IP data requires more caution and takes more time than resistivity measurements. Nevertheless, IP reduces ambiguity compared with a DC resistivity measurement.

Nuclear magnetic resonance (NMR)

Nuclear Magnetic Resonance (NMR) measurements quantify molecular properties of matter by exposing atomic nuclei in a magnetic field to electromagnetic radiation. NMR is particularly sensitive to the presence of protons ^1H and is therefore well suited to investigate systems containing water. In soil science, NMR is used to infer permeability, water content, total porosity, pore size distribution and to quantify bound and free fluid fractions. Under an external magnetic field, protons behave like small bar magnets that orient themselves along the direction of the magnetic field. In doing so, they create a macroscopic magnetization (step 0 in Fig. 7) whose magnitude is directly proportional to the proton density and, by extension, to the water content. NMR measurements are classically achieved by producing an oscillating magnetic pulse with a transmitting current coil at a particular frequency known as the Larmor or resonance frequency which tips the magnetization away from the external magnetic field (step 1 in Fig. 7). The resulting transverse magnetization creates in turn a small signal that can be measured by a receiving current coil. When the excitation pulse is switched off, the amplitude of the measured current decreases rapidly while the system progressively returns to equilibrium (steps 2 and 3 in Fig. 7). The amplitude of the signal just after the excitation pulse is directly related to the water content. The relaxation time is influenced by multiple parameters including the pore size distribution. For more information about the NMR principles and applications for near-surface characterization, the interested reader is referred to Behroozmand et al. (2014).

Challenges and limitations

While borehole NMR has long been successfully used to characterize gas and oil reservoirs (Freedman, 2006) and more recently for near-surface hydrogeological and environmental studies (Kirkland and Codd, 2018), surface NMR still remains relatively little used outside the research community, despite its great potential, mainly because of its low signal to noise ratio. To overcome this, further development of the technique is needed. Possible areas of improvements include electromagnetic noise reduction (Kremer et al., 2022) and more efficient instruments and measurements techniques to increase production rate (Behroozmand et al., 2014). Interesting instruments for soil science are, for example the DART system, a slimline borehole NMR, or the single-sided DISCUS equipment.

Seismic methods

Seismic methods involve the measurement of wave-fields produced by artificially or naturally-generated seismic waves that propagate in the subsurface or near the soil surface. An earthquake is a common form of a seismic wave. Typically, seismic measuring arrays involve a transect of seismic sensors (geophones) deployed on the soil surface or along boreholes, and a seismic source is successively activated at different spatial locations. In soil applications, the source often is a hammer impact on a plate (see Fig. 8). The geophones measure the ground movement resulting from body (including pressure and shear) waves propagating through the soil, scattering at soil interfaces and from surface waves propagating at the soil surface. Pressure waves are the fastest seismic waves, produce soil displacement parallel to the direction of propagation and are the smallest in amplitude.

Fig. 7 Protons behave like small bar magnets called spins. Under the effect of an external magnetic field (e.g., the earth's magnetic field), they tend to orient themselves in the direction of the field creating a macroscopic (so-called longitudinal) magnetization (blue arrow in step 0). The amplitude of this magnetization is directly proportional the proton density and therefore to the water content. However, the longitudinal magnetization cannot be quantified as long as it is oriented along the direction of the external field. Therefore, it needs to be tipped away from it. This is achieved by applying an excitation pulse at a particular frequency called the resonance or Larmor frequency (step 1). The resulting oscillating transverse magnetization (green arrow in steps 1 to 3) generates a small signal which in turn can be detected by a receiver coil. At the end of the excitation pulse, the spins progressively realign along the external magnetic field (blue arrow pushes back) and a loss of spins synchronization progressively occurs (green arrow decays)(steps 2 and 3). This results in a decrease of the received signal.

Fig. 8 Basic principles of seismic measurements.

Relative to pressure waves, shear waves and surface waves are slower (both travelling at a similar velocity) but produce higher amplitude soil displacement that is perpendicular to the direction of propagation. Seismic velocities depend on properties of the bulk soil such as resistance to compression and to shear stress, but also on soil moisture and capillary pressure (Romero-Ruiz et al., 2018). For this reason, they provide a direct link to soil mechanical properties (e.g., penetration resistance).

Seismic characterization and imaging of soils can be achieved using a wide variety of methods addressing wave phenomena including refraction and reflection of pressure waves and dispersion of surface waves (Steeple, 2005). High amplitude surface waves dominate the seismograms and there is an increased interest in their application for characterizing soils (e.g., soil compaction and permafrost monitoring (Dou and Ajo-Franklin, 2014)). Nevertheless, pressure waves are the first arriving waves in the seismograms, are easy to detect and, thus, methods that target them are simpler and the most used. For example, seismic refraction tomography, is used to infer a subsurface map of pressure wave velocities (Sheehan et al., 2005). It measures the travel-time of pressure waves that propagate through the soil and are refracted back to the surface after interacting at soil interfaces (e.g., layers). The travel-times are extracted from seismograms and used to infer a pressure wave velocity subsurface map that explains such observations.

Challenges and limitations

Seismic methods are underused in soil applications mainly due to limitations in survey design and interpretation tools. Geophones need to be buried to sense ground movement, and located close to the seismic source (decimeters or a few meters) to achieve the necessary vertical resolution and avoid attenuation; which limits acquisition at large scales. Unlike other geophysical methods, automatic seismic acquisition has seldom been developed nor tested. These restrictions further limit the capacity to monitor active seismic signals over time. In addition, for such small scales, simultaneously arriving pressure, shear and surface waves overlap in the recorder seismograms and are often difficult to disentangle for individual interpretation. Despite the limitations identified, the direct dependence of seismic waves on the soil mechanical properties makes seismic methods highly relevant for soil studies, given that they can resolve mechanical states that are not directly observable by other more commonly used geophysical methods (e.g., ERT, EMI and GPR).

Distributed temperature sensing (DTS)

Distributed Temperature Sensing (DTS) provides temperature measurements at high spatial and temporal resolutions (each 5 to 60 s at 0.1–2 m spacing) along a fiber optic (FO) cable at scales of meters to tens of kilometers. Fig. 9A shows the measurement principle of DTS. The measurement unit emits short laser pulses into the fiber optic cable. As the light pulse travels, a portion of the photons interact with the crystalline structure of the optical fiber, resulting in a backscattered signal returning back toward the DTS unit. As detailed in Fig. 9B, the backscattered signal spectrum has Rayleigh band, Brillouin bands, and Raman bands. Most DTS systems estimate temperature from the Raman backscattering signal, by measuring the returning signal at two distinct wavelengths: the Stokes (-Raman) component and to the anti-Stokes (-Raman) component. Contrary to the Raman Stokes component, the intensity of the Raman Anti-Stokes component depends on the temperature of the surrounding soil. The temperature is estimated from the ratio of the amplitudes of the Stokes to the Anti-Stokes signals. The time of arrival of the backscattered light signal depends on the location of the measurement along the fiber, thus leading to the exact measurement location.

Both passive- or active-DTS surveys are possible (or both methods combined). Passive-DTS continuously monitors natural temperature variations all along the fiber optic cable, while active-DTS surveys monitor induced temperature changes by injecting an artificial heat source in the soil or cable. Soil temperature is particularly variable in time and space. Passive-DTS is a great tool to monitor those spatio-temporal temperature dynamics at high spatial and temporal resolutions over long distances. In addition, both passive- and active-DTS experiments can be used to estimate soil thermal properties. As soil thermal properties depend on moisture content, monitoring temperature changes through fiber optic DTS not only provide estimates of thermal conductivity (Abesser et al., 2020), and thermal diffusivity but also of soil moisture content (Ciocca et al., 2012).

Challenges and limitations

While active-DTS measurements have been used effectively to estimate soil thermal conductivity, their use to estimate water contents and soil heat capacity or diffusivity remains challenging. One of the reasons is the structure of fiber optic cables, which influences the temperature increase for early periods in time of heating, and affects the analysis of the thermal response curve, used to estimate thermal properties and water contents. This issue can be addressed by applying longer heating and cooling periods. Unfortunately, prolonged-time heat injection can significantly disturb the soil water content field and then reduce the accuracy of the soil water content estimate (Wang et al., 2020).

One of the main limitations to using this method to study soil thermal properties is that the deployment of fiber optic cables in soils may significantly disturb their structures and lead to preferential pathways for infiltration. Hence, FO-cable installation is a critical point for field soil applications of DTS methods. Since heat transfers are different in soils and in water or air, the contact between the soil and the cable must be perfect to avoid air and water pockets, that highly affect temperature response. Likewise, accurate estimates of the depth installation of the cable are required, especially to estimate soil properties from passive-DTS measurements (Steele-Dunne et al., 2010). To do so, plows can be used to ensure the proper installation of the cable and control its burial depth (Simon et al., 2022).

Fig. 9 (A) Principle of FO-DTS measurements. (B) Spectrum of the backscattered light returning back toward the DTS unit. Apart from the Rayleigh band which has the same wavelength as the incident laser pulse, the backscattered signal is shifted toward higher and lower wavelengths, called Stokes and Anti-Stokes components respectively. Stokes and Anti-Stokes signals result from Brillouin and Raman scatterings. Brillouin Stokes and Anti-Stokes components are both sensitive to strain (ϵ) and temperature (T) variations whereas, for Raman bands, only the amplitude of the Anti-Stokes component is temperature-dependent.

Forward modelling and inversion

Most of the measured geophysical properties are 'apparent', i.e. represent a volume-average of heterogeneous soil properties for a given arrangement of emitters and receivers. Those apparent properties require a data inversion process (see Fig. 10) to obtain an estimation of their 'real' distribution in the soil. In such a process, we use a 'forward model' which simulates the measurements one would measure for a given distribution of subsurface properties. Once we have those simulated data, we compare them with the real data. This comparison is typically done with an objective function, which we minimize iteratively by running the forward model again for different properties of the subsurface (obtained, for instance, by using the gradient of the objective function with respect to the model properties) until the difference between the simulated and real data is minimal. In many cases, several distributions will fit the data equally well, so most inversion algorithms have to add additional constraints (e.g., a smoothness constraint) in the objective function to select the final estimated distribution.

In addition, the sensitivity, resolution and scales of the different geophysical methods can vary significantly. A combination of techniques is, therefore, often necessary to extract variations of one specific soil property or state variable. Instead of treating every data source independently, translating them to soil properties or variables and using that for interpretation, they can be combined in a joint interpretation scheme. Hinnell et al. (2010) discussed several approaches in which geophysical data and models and hydrological models are more or less coupled, so that the physics of the soil system can constrain the interpretation of the geophysical data.

Attempts for joint inversion of geophysical methods only started to be reported in the last 15–20 years. Yaramanci et al. (2002) used the optimization method of simulated annealing to jointly invert SNMR and vertical electrical sounding data for both synthetic and real cases, eventually inferring mobile and immobile water contents. Doetsch et al. (2010) used time-lapse borehole ERT and GPR to track an injected saline plume. They looked at the coupling between the two methods through constraints in the inversion scheme. Jardani et al. (2013) combined ERT and SP in a stochastic framework, i.e., looking for property statistics rather than its actual deterministic distribution. In their case, the inversion was of the hydrological problem (flow and transport model, looking primarily at the hydraulic conductivity).

Fig. 10 Schematic overview of a forward modelling and inversion pipeline in geophysics.

Data standardization and open science

Several geophysical methods originated from the commercial oil and mineral exploration industry. As such, instruments are mostly closed source and often lack standardization, manufacturers tending to produce instrument-specific data formats. On the hardware side, the black box model of commercial instruments can sometimes be a barrier. For instance, EMI instruments often need to be corrected for drift and calibration on top of the manufacturer calibration and without knowing about the hardware-born causes of the drift. Another example is from GPR systems that typically provide no information about the emitting source. More transparency on the internal specifications of commercial instruments and open hardware instruments (e.g. OhmPi resistivity meter) built on top of open-source platforms (e.g., Raspberry Pi, Arduino) could alleviate these issues.

Geophysical data is increasingly processed using open-source software. These software packages can be bound to a geophysical method, such as the open-source FDEM1DFWD or FEMIC codes that propose forward models for electromagnetic induction. Alternatively, multi-method geophysical frameworks such as SimPEG or pyGIMLI enable processing of different types of geophysical methods together (coupled or joint inversion). Other open-source projects such as ResIPy, EMagpy, GPRpy propose a graphical user-interface to process resistivity, EMI and GPR data respectively. This makes them more accessible for non-specialists and in an educational context. The Software Underground (<https://softwareunderground.org/>) project summarizes several initiatives about open-source software for geophysics.

One of the main challenges of geophysics for soil applications remains the use of pedophysical relationships to link geophysical variables to soil properties. These relationships are often site-specific, can present hysteresis and are subjected to heterogeneity. Building worldwide databases of pedophysical relationships from lab and field measurements can help in building more robust relationships but also to develop standards (e.g., Catalog of AgroGeophysical Studies, <https://agrogeophy.github.io/catalog/>).

Conclusion

Geophysical techniques map a wide range of proxies for soil properties and state variables. Through this capacity, geophysical data complement precise (invasive) measurements with 2- or 3-D continuous information, while equally bridging the gap between point observations and coarse satellite data. Their non-invasive character allows for timelapse surveys for monitoring programs.

Despite these advantages, the multiscale heterogeneity of soils burdens the interpretation of geophysical data, exacerbating, for instance, the use of pedophysical relationships to quantify specific soil properties. To advance the application of soil geophysics, more data and measurement standards are needed, alongside benchmarking of processing algorithms and open science initiatives.

Nevertheless, as the sole means for non-invasive soil investigation over a large depth range, it is unthinkable to imagine geophysics apart from soil science. As an integral part of field research, especially combined with complementary data types, the use of geophysics in soil applications will grow more relevant with time.

Abstract

Non-invasive imaging techniques provide a unique ability to investigate soil processes with minimal disturbance to its natural state. This chapter provides an overview of the key non-invasive techniques, their operating principals and their areas of application to quantify soil processes. e.g. structural development of soil pore networks, plant root system architecture, rhizosphere interactions, water and chemical movement. The digital nature of the data integrates well with structural modelling approaches of soil processes from both laboratory and field-based experiments.

Key points

- Non-invasive imaging allows for direct quantification of soil structure and associated measures of processes in three dimensions
- Collection of 3D digital data of soils either field structured or repacked facilitates modelling of soil process
- Combination of different modalities at multiple scales, using correlative imaging approaches, offer exciting prospects for understanding the physical, chemical and biological behavior of soils in the future

Introduction

The study of soil pore structure and its impact on many soil processes has historically relied on the use of indirect measurements (e.g., soil water retention characteristic, nitrogen sorptivity and mercury porosimetry), primarily due to the inherent opacity of the soil matrix. Such methods tend to simplify the system, assuming that pores are cylindrical in shape and therefore overlook the complex heterogenous nature of the soil ecosystem. Direct imaging approaches to quantify soil pore micromorphology based on the use of soil thin sections have been widely used since the 1940s. However, the preparation of soil thin sections is highly laborious, destructive and generates often discontinuous 2D images, producing limited information on the connectivity of pore networks. Over the last few decades, there has been significant development and application of non-invasive imaging techniques, which have proved to be invaluable in gaining new insights and understanding of processes in soil. For example, the role of soil structure, operating across spatial and temporal scales, has a direct consequence on processes such as gas and water flow, plant root development, root water and nutrient uptake, carbon and nutrient cycling and biological activity (Young et al., 2001). The multiple interactions between these processes mean that soil structure is dynamic with the connectivity, tortuosity and heterogeneity of the 3D soil pore network changing over time. The study of such processes therefore requires methods that capture the 3D nature of the soil system. There are several different non-invasive techniques, each with their own advantages, for studying different parts of the soil system. In this chapter, the main non-invasive imaging techniques to assess soil processes in 3D will be introduced and an overview of their key principles, strengths, and main applications to soils will be provided. These techniques are Computed

Fig. 1 Applications of 3D non-invasive imaging techniques to soil processes.

Tomography (CT), Magnetic Resonance Imaging (MRI) and Positron Emission Tomography (PET). Each of these three methods differ in the way they generate images of the material under investigation as well as their potential applications. Fig. 1 provides an overview of some of the key areas of application of each of these techniques. Geoelectrical methods, such as Electrical Resistivity Imaging (EIT), which by proxy can non-invasively measure the spatial and temporal variability of soil processes especially in the field will not be covered in this chapter. Please see Loke et al. (2013) and Cimpoiu et al. (2020) for reviews of EIT.

Computed tomography

Computed Tomography (CT) is a non-invasive imaging technique that allows the measurement of the interior and exterior structure of an object in three dimensions. The technique is based on calculating the attenuation of a radiation source as it passes through a sample. A series of projection images at incremental angles through the sample are collected and then mathematic algorithms are used to compute multiple cross-sectional images that map the attenuation of the incident radiation. Post scanning, computer workstations are used to run the algorithms in a process known as reconstruction. The name tomography is derived from the Greek words tomos, meaning 'to slice or section' and graphein, which means 'to write.' There are different forms of CT defined by the type of radiation that is used to collect the images e.g. X-ray, gamma or neutron tomography. As each type of radiation has different interaction properties with the constituent materials of the sample, each type of CT offers a range of application purposes in the study of soil processes.

X-ray computed tomography

X-ray Computed Tomography (XCT) is the most commonly used non-invasive imaging technique in soil science. It was originally developed as a medical diagnostic tool in the late 1960's by Sir Godfrey Hounsfield who designed the first commercial whole-body medical CT scanner (EMI Mk1) in 1972.

Key principles

X-ray Computed Tomography allows measurement of the X-ray attenuation coefficient of a material (e.g. a soil core) by calculating the reduction in intensity of an incident X-ray beam (I_0) to that which has been transmitted through the material under investigation (I). This relationship is described by Lambert-Beer's law:

$$I = I_0 \exp(-\mu D) \quad (1)$$

where μ is the linear X-ray attenuation coefficient (L^{-1}) and D is the thickness of the material (L^{-1}). The linear attenuation coefficient (μ) is a function of the energy of the incident X-ray beam and both the physical density and atomic number of the constituent components of the material. As soils fundamentally contain multiple phases in nature, Eq. (1) can be extended to account for the differences in the linear attenuation coefficients for air, water and solid components of the soil:

$$I = I_0 \exp \left(- \left[(1 - \theta_p) \mu_s \rho_s D + \theta_p S_w \mu_w \rho_w D \right] \right). \quad (2)$$

ρ_s and ρ_w are the densities and μ_s and μ_w are the linear attenuation coefficients of solid and water, respectively. θ_p denotes the total porosity and S_w the water saturation. As air has a very low attenuation and therefore a negligible contribution to the overall linear attenuation coefficient it is omitted from the equation.

Types of X-ray CT system

There are three main categories of X-ray CT system; medical, industrial and synchrotron based (Fig. 2). Each of these categories have a slightly different configurations but share four common components (i) X-ray source (either conventional X-ray tube or synchrotron light), (ii) a sample manipulator stage or gantry, (iii) an X-ray detector, and (iv) a computer for acquisition,

Fig. 2 Examples of different types of X-ray-based Computed Tomography system. (A) Medical CT scanner at Queens Medical Centre, Nottingham, (B) Industrial X-ray CT system at Hounsfield Facility, University of Nottingham, (C) Internal components of industrial CT system ([right to left] X-ray tube, soil core in rotating stage and detector panel) and (D) Synchrotron Light Source Facility where tomography is one of the many techniques used for investigation of samples. reconstruction, and downstream analysis of the image data. The configuration of these components has important consequences for the size of object that can be scanned and the spatial resolution of the images. Imaging resolution is dictated by the size of the X-ray beam focal spot, the size and number of pixel elements of the detector, and the distances of the detector and the sample from the X-ray focal spot. As medical CT systems are designed around imaging a human body (meter to decimeter size range), the source-object-detector configuration differs from that of industrial and synchrotron-based CT, where the X-ray source and detector rotate around the sample (patient), whereas it is the sample that rotates on a manipulator stage with source and detector remaining static in the latter two (Fig. 2C). Medical CT resolution is generally limited to 1–2 mm, so most applications of CT to soil science in the last 10 years use industrial or synchrotron-based systems. These generally offer a higher spatial and contrast resolution, which permit discrimination of individual soil phases, enabling the resolution of microscopic pore characteristics (often with feature recognition $<2\text{--}3\text{ }\mu\text{m}$). However, with increasing levels of spatial resolution the field of view of the scan is generally reduced. For example, typical scanning resolution of a 5 cm diameter soil core would be approximately $20\text{--}30\text{ }\mu\text{m}$ on an industrial CT system. However, to image at higher resolution (e.g. $<5\text{ }\mu\text{m}$) a much smaller, ‘soil aggregate scale’ sample would be needed. A wide range of industrial CT systems are now available in the marketplace that offer versatility in sample size, resolution and X-ray power. Furthermore, with synchrotron light systems and some industrial systems (e.g. 3D X-ray microscopes), optical magnification is possible to enhance image sharpness and resolution. In some cases, advanced scanning modes are available in these systems which allow higher magnification scans of a larger object (e.g. region-of-interest scanning). For industrial and synchrotron systems, the X-ray source, stage, and detector are housed within an appropriately shielded lead cabinet or ‘hutch’ to prevent accidental exposure of the operator of the system to ionizing radiation. A further description of the key parts of an X-ray CT system is provided below.

X-ray source

X-rays are generated by either an X-ray tube or a synchrotron light source. X-ray tubes used in medical or industrial CT are mostly based on the Coolidge tube, also known as a hot cathode tube, where the thermionic effect is used for electron production. The evacuated chamber of the tube contains a cathode and anode. The cathode is a tungsten wire filament that is heated by the supply of a low voltage from a generator to release electrons. By application of a high voltage between the cathode and anode the electrons are accelerated to strike the anode (target) at the end of the tube. As the electrons enter the electric field of the anode material atoms, they are rapidly slowed down resulting in a loss of their kinetic energy and release of X-ray radiation and heat. This radiation is called *bremsstrahlung* (German for braking radiation). Secondly, characteristic radiation is also produced if an accelerated electron directly strikes and ejects a bound electron from the inner atomic shell of the anode material. X-rays are produced when an electron, from

the outer atomic shell, falls back to the inner shell due to its reduction in energy. X-ray tubes can be supplied with an anode made from different materials (e.g. tungsten, molybdenum, copper) which will produce characteristic radiation with a different energy spectrum. This is useful depending on the composition of the sample to be investigated as molybdenum or copper targets can be used to image materials with lower densities such as plant tissue. The combination of the two processes of X-ray production result in an X-ray beam that is polychromatic, thus displaying a range of wavelengths (and therefore energies) depending on the maximum acceleration voltage and current of the electron beam and the anode material.

X-ray tube type in industrial CT systems are defined by whether the electron beam is transmitted through or reflected off the target. Transmission tubes offer a greater level of control and precision to focus of the electron beam to achieve sub-micron focal spots size, providing benefits in image sharpness for imaging at high resolutions (0.5–2 μm). However, they are limited in power and therefore not as well suited for larger samples where higher X-ray energies and flux are required to fully penetrate the sample. Micro-focus (e.g. focal spot typically $>3 \mu\text{m}$) CT systems typically have a reflection target X-ray tube which is positioned at an approximate 45° angle inside the cabinet and the electron beam is reflected off the surface of the X-ray target (Fig. 2C). Generally, higher power X-rays are required to penetrate larger samples or samples consisting of more electron dense materials. For example, using an industrial system, although the X-ray tube energy may be in the 70–120 kV range for a small soil aggregate (2–5 cm diameter), much higher energies (approximately 150–200 kV range) are required to achieve sufficient X-ray penetration for larger soil cores (e.g. 5–10 cm diameter). Many industrial CT manufacturers now offer to supply their system with dual tube configurations, thereby extending the operational functionality of the system and permitting both nanofocus and microfocus imaging capability.

Synchrotron light sources are a type of electron accelerator that produce very high brilliance X-rays. The generated X-ray beam is parallel (unlike cone or fan beams) and can be tuned to a specific wavelength (monochromatic) to enhance the image quality beyond what is capable on a lab-based industrial CT system. There are >50 synchrotron light facilities globally which range in size (main storage ring can be 0.5 to >2 km in circumference) and energy level. For example, Diamond Light Source, UK (<http://www.diamond.ac.uk/>), is a medium energy level source (3 GeV) with a main storage ring circumference of 562 m, and 33 beamlines (see Fig. 2D). Each beamline is allocated to a different type of experimental technique which broadly falls into three categories (diffraction, imaging or spectroscopy). In addition to tomographic imaging of soil structure, synchrotron beamlines can be used to map the chemical soil environment using absorption, fluorescence and diffraction spectroscopy techniques often with ultra-high elemental sensitivity and resolution (nanoscale). Detailed reviews of soil, plant and environmental science applications using synchrotron light are provided by Burke et al. (2015) and Lombi and Susini (2009).

Manipulator stage

The manipulator is used to securely hold and position the sample during the scan. It consists of a mechanical multi-axis CNC stage. The stage allows rotation of the sample to enable collection of a series of projection images at different oblique angles to the X-ray source. In industrial systems magnification is geometric so moving sample closer to the X-ray source will result in a higher magnification. Motion in the vertical axis facilitates imaging of longer samples such as soil cores.

Detector

Measurement of X-ray attenuation by the sample is achieved using an X-ray detector. The detector essentially captures X-rays and converts their intensity into an electrical signal. There have been significant advances in detector technology, especially in recent years. In modern industrial X-ray CT systems, flat-panel scintillation detectors are most common. These detectors offer higher sensitivity, improved signal-to-noise and quantum efficiency, larger dynamic range and increased number and size of the individual pixels compared to previous generation of scanner. All these factors contribute to improved spatial and contrast resolution, enhanced feature detection capabilities and ever faster scan times.

Image analysis

Irrespective of imaging modality, a key part of all non-invasive imaging techniques is the discrimination of discrete phases in the images. Broadly in soils, these phases are air (pores), water and solid material, however the solid material may consist of a wide range of materials from primary soil particles (sand, silt and clay) to plant roots, seeds, residues, particulate organic material and macroinvertebrates. With CT, the reconstructed images which map the X-ray attenuation co-efficient of these phases, are typically represented in either 8, 16 or 32-bit grayscale image format, with low attenuating materials (e.g. air) corresponding to low gray values and highly attenuating (e.g. mineral grains with high atomic numbers) corresponding to high gray values (e.g. for an 8-bit grayscale CT image low attenuation [0 = black] to high attenuation [255 = white] (See Fig. 3). The number of individual images depends on the number of pixels of the detector and generally range between 1000 and 3000. The spatial structure of the soil pore network and other components can be visualized and quantified using 3D image analysis techniques (Fig. 4). This typically follows a series of stepwise processes involving image contrast enhancement, noise reduction, material segmentation or thresholding (via pixel classification), quantification and visualization (See Fig. 5). There are numerous different methods of noise reduction and threshold algorithms available and the final numerical output of the image analysis workflow is heavily dependent on each of these steps, especially the choice of thresholding algorithm (e.g. see Baveye et al. (2010)). Therefore, caution must be taken to ensure the image analysis workflow is appropriate for your own images and specific application as differences in soil properties (geological background, texture, moisture, and organic matter content) and scanner settings can impact on accuracy of the measurements. In the last 5 years, the development of artificial intelligence methods based on convolutional neural networks have become increasingly

Fig. 3 Example X-ray CT slice images (XY slice (left) and ZY slice image (right)) showing soil structure of a loamy sand soil core collected from WITS Rural Facility, South Africa (40 mm diameter x 50 mm depth). Low image gray levels (dark) relate to lower density materials (e.g. air, organic matter) whereas higher image gray levels relate to higher density materials (primary particles). The annotations highlight some of the key features in the images (A) primary particles (sand grain), (B) primary particle with higher density inclusions, (C) bulk soil matrix, (D) air-filled biopore, (E) inter-particle porosity, (F) plant roots, (G) organic residues (H) in-filled biopore. (A) Gray scale 3D rendered image of solid material, (B) quantification of soil pore volume calculated using VGStudioMAX defect analysis module (Volume Graphics GmbH, Germany) and (C) soil pore thickness calculated using *BoneJ* plugin for *Fiji* image analysis software. Scale bar 10 mm.

popular and offer advantages in fully automated segmentation of image data of soils and plant roots (Han et al., 2019; Soltaninejad et al., 2020). To extract the wealth of quantitative information about the tortuosity, connectivity, and topology of the features of interest, a number of 3D software tools and approaches are available. Commercial analysis packages such as *Avizo* (ThermoFisher Scientific, USA), *VGStudioMax* (Volume Graphics GmbH, Germany) or *Dragonfly* (Object Research Systems, Canada) offer versatile solutions for advanced processing of CT data, however their high cost can be a limitation for some users. Opensource free software such as *ImageJ/Fiji* (Schindelin et al., 2012), which has collections of community developed plugins specifically designed for analysis of 3D porous networks (e.g. *BoneJ* (Doube et al., 2010)), soils (e.g. *SoilJ* (Koestel, 2018)) and plant roots (e.g. *Rootline* (Phalempin et al., 2021)) provide useful alternatives to commercial packages. As the image data are digital, the information lends itself well to translation for modelling approaches, where structural models are required.

For further reading, Schlüter et al. (2014) provide an excellent in-depth review of imaging processing of multiphase CT images appropriate to soil processes.

The *Li* local threshold algorithm in FIJI Software was used in this example. Histograms of image gray levels are presented below each image.

Gamma-ray tomography

Another type of tomography used in the soil sciences is Gamma-ray tomography. It is similar in fundamental principles to X-ray CT, but as the name suggests, measures the attenuation of gamma-rays as they are transmitted through the sample of interest. Gamma-rays are emitted by the nucleus of certain radionuclides following radioactive decay. Commonly used sources are ^{241}Am , ^{133}Ba , ^{137}Cs , and ^{60}Co , with each radionuclide displaying different gamma-ray emission energy, activity, and half-life properties. Gamma-ray tomography has not been used as extensively as X-ray CT in soil science. Gamma-ray CT systems are often smaller, simpler, more portable, less expensive, have greater penetrating power and less scatter in comparison X-ray CT systems that typically require large electrical generators to power their X-ray tubes. However, the acquisition radiograph images are generally of lower quality due to limitations on the intensity of the gamma-rays from the radioactive source. Overall scan times can be therefore longer due to the need for longer detector exposure times. For further reading, [Pires et al. \(2011\)](#) provide an excellent review of the use of Gamma-ray tomography in soil science and [Johansen \(2015\)](#) give a detailed overview of the technology and some general applications.

Neutron tomography

Neutron tomography is a non-invasive imaging technique that uses neutrons to map the internal structure of a material of interest in 3D via their attenuation of neutrons. The acquisition principles are similar to those used for X-ray and Gamma-ray CT. However, as neutrons have a neutral charge, they generally have a very weak interaction with some electron dense materials. In comparison to X-rays, which are mainly attenuated by the electron shell of atoms, the attenuation of neutrons is dominated by interaction with the atomic nuclei, so lighter, nucleon dense elements such as hydrogen and boron have a much stronger interaction with neutrons compared to heavier elements such as silicon, aluminum or lead. Neutron imaging has several advantages as compared to other imaging techniques. These advantages include the ease of differentiation of roots as they contain water, making them distinct in neutron radiographs. Neutron tomography can also enable the tracking of water movement and uptake as it can differentiate between isotopes of hydrogen (protium and deuterium) which can be used to track water movement in real time imaging ([Zarebanadkouki et al., 2013](#); [Tötze et al., 2021](#)). One of the major disadvantages with neutron tomography is the limited penetrating power of neutrons, which limit the thickness of specimens that can be successfully imaged (limited approximately 20 mm in soils) ([Mawodza et al., 2020](#)). Exposing study specimens to neutrons also makes them radioactive soon after imaging, thus introducing handling hazard for up to a few hours. Another limitation that may reduce the widespread use of neutron imaging is the relative scarcity of imaging facilities. Most neutron imaging facilities are based at neutron research reactors or spallation sources such as Paul Scherrer Institut in Switzerland (www.psi.ch/en/num) or the ISIS Neutron and Muon Source at the Rutherford Appleton Laboratory in UK (www.isis.stfc.ac.uk).

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is a valuable non-invasive tomographic technique used for the investigation of soil processes involving the distribution or movement of water. It can also be applied to image plant tissues, as they are predominately water

based. In comparison to the electromagnetic waves and high-energy particle transmission techniques described above, which measure the absorption of ionizing radiation by the sample, MRI is emission-based and uses the effect of nuclear magnetic resonance (NMR) of certain atomic nuclei (mainly hydrogen and therefore water) to generate 2- or 3-D images. MRI scanners use a strong magnetic field to align the spin (angular momentum) of the hydrogen nuclei (protons), creating weak magnetization of the sample. This magnetism can be manipulated with application of time-dependent radio frequency pulses. A detector coil around the sample is used to measure the change in orientation of the rotational axis of the spinning nuclei (called precession) through induction of a weak voltage. Fourier analysis is used to extract spatial information on the distribution and quantity of protons from the detector coil signal. For an accessible introduction to the principles of NMR we refer the reader to Scheenen et al. (2000) and to Callaghan (1993) who provide a thorough description of the theory of the technique.

The application of MRI to characterize moisture content in soils was first demonstrated in the 1980s, both in the field and the laboratory, identifying its potential as for studies of preferential flow pathways. The use of tracers with fluorinated compounds or paramagnetic ions like Cu^{2+} , Ni^{2+} or Mn^{2+} can be useful to improve the contrast of water. Fig. 6A shows an example of the temporal mapping of water flow in a soil core using MRI (Haber-Pohlmeier et al., 2021).

Soils with strong magnetic properties (ferromagnetic particles) can present a challenge to MRI as they suppress the signal of the soil water. However, Pflugfelder et al. (2017) screened six different agricultural soils with a range of textures for use in a MRI study to image barley roots. Only one of the soils proved unsuitable for use with MRI, highlighting the potential of the technology for studying plant root growth (see Fig. 6B for an example of root imaging) in a range of natural soil types (van Dusschoten et al., 2016). Despite this, there are still relatively few studies using MRI to look at root-soil interactions, especially compared to X-ray CT. The method gives detailed information on root traits such as mass, length, diameter, tip number, branching angles, spatial distribution, and growth rate. Detection of roots with diameters down to 200 μm is possible and the technique also allows simultaneous measurement of moisture content in the soil surrounding roots. Recently, low magnetic field MRI has been developed to further

Fig. 6 Examples of MRI imaging of soil and plant processes. (A) Imaging flow in a natural soil core during irrigation. (i) Setup. (ii) ZTE image of the natural core (maximum intensity projection) with no irrigation. Matrix size 128^3 , FOV: $70 \times 70 \times 90$ mm. The dotted orange line indicates the soil surface, the white arrows point to the large wormhole and a smaller macropore, probably caused by a degraded root. (iii–v) Central vertical slice with different irrigation rates (top to bottom) and time-points after start (left to right). Shown are difference images at the given time-points minus $t = 0$. The red arrow indicates ponding water near the left edge. The black arrows indicate film flow at the walls of the large wormhole. mitigate the effects of paramagnetic materials in soil on image quality further extending the utility and wider use of technique for the study of root-soil interactions (Bagnall et al., 2020).

Positron emission tomography

Although less widely used compared to CT, Positron Emission Tomography (PET) allows unique insights at high sensitivity of dynamic processes in soils. The technique involves the introduction of a positron-emitting nuclide tracer to the soil or plant system and then maps its spatial and temporal distribution. Tracer location is detected by the emission of paired high-energy photons (as gamma-rays) which are produced following an annihilation event due to the interaction of a positron from the tracer and an electron of the sample material. The emitted gamma rays are detected by arrays of scintillator crystal detector blocks arranged in a ring or stack of rings in the scanner. Although the spatial resolution of most PET scanners is in the 1–5 mm range, due to the physics of the emission, and the detection of the coincident photons, PET imaging has very high sensitivity and accurate estimation of radiotracer concentration. Several positron-emitting isotopes can be created which have potential applications in studies of soil and plant processes. The most commonly used are ^{11}C , ^{13}N , ^{15}O , ^{18}F and ^{64}Cu . For example, both ^{18}F labelled fluoride (F^-) and fluorodeoxyglucose (FDG) have been used to image water transport in soils and sediments, however, each of these compounds have different physiochemical properties compared to water so caution must be taken on interpretation the results. Solute transport (Richter and Grundig, 2000) and herbicide migration (Kulenkampff et al., 2018) in soils has also been successfully visualized using ^{64}Cu labelled compounds. PET imaging has also allowed in situ quantification of biological activity within soils. Kinsella et al. (2012) used ^{18}F labelled FDG to characterize the metabolic activity of a subsurface strain of *Rahnella* (sp. Y9602) that has been shown to promote uranium sequestration in groundwater and soils. The tracer is metabolized by the bacteria and can be spatially resolved in the experimental system, which consisted of a column of fine sand with two bands of slit loam soil. The results showed a higher activity in the finer textured silt loam (see Fig. 7A). PET has also showed promise for quantification of microbial activity in soil sediments and crusts. In plant science, PET has been used extensively to image dynamics of macronutrients, trace elements, and signaling compounds (see Fig. 7B). Furthermore, the combination of PET with X-ray CT (Garbout et al., 2012) and MRI

(Jahnke et al., 2009) based imaging, information of the porous structure of soil can be generated in combination with root structure and the movement of the radio tracers in the plant, opening exciting new opportunities to aid understanding of the rhizosphere. For further reading on the use of PET imaging in the soil and plant sciences see (Schmidt et al., 2020).

Applications

Both X-ray and Gamma-ray CT have been used to investigate; fluid transport in relation to the physical structure of a soil (e.g. porosity, pore size distribution, surface area); generate data for simulation of fluid flow into a soil and other porous media and to measure the impact of pore microstructure on permeability in addition to measurement of soil quality indicators bulk density and total porosity. By far the most widely applied use of CT is in the 3D quantification of soil structure, where soil scientists have investigated the effects of land and crop management, impact of plant roots, microbes, macroinvertebrates on structural genesis (e.g. see Helliwell et al. (2013) for further examples). X-ray CT has also been used extensively for the quantification of the 3D structure of plant roots and their development over time (Mooney et al., 2012). Although, X-ray CT offers the potential of imaging plant root structures at higher spatial resolutions (e.g. $<5\ \mu\text{m}$ resolution imaging of root hairs using synchrotron based X-ray CT (Koebernick et al., 2017)), differentiation of roots in the soil is still a major challenge due to common X-ray attenuation values with other material in the soil such as water filled pore space and organic based residues. The use of Neutron, Magnetic Resonance and Positron Emission imaging techniques offer alternative approaches with greater sensitivity for plant root imaging although the imaging resolution is coarser.

Summary and outlook

This chapter has outlined the use of three of the main non-invasive imaging techniques currently available to investigate soil processes in 3D: Computed Tomography, Magnetic Resonance Imaging and Positron Emission Tomography. Although there have been significant advances in the development of each of these techniques over the last 30 years, there are still a number of gaps in understanding of soil processes that need to be addressed. In terms of CT, the wider availability of industrial CT systems, due to their lower cost and easier intuitive operational protocols, bring the technology to a greater number of soil scientist where equipment may become a standard tool in the soil science laboratory. Advances in X-ray detectors have facilitated improved image quality and ever faster acquisition times, giving the soil scientist the ability to increase sample replication numbers to give greater confidence in capturing the heterogeneity displayed by 3D pore networks. Advanced imaging capabilities at national synchrotron light facilities also offer combined use of different modalities. For example, X-ray CT and time-of-flight neutron imaging was recently shown to offer greater discrimination and localization of structural phases in soils (soil minerals and soil organic matter) than if the techniques were used independently (Koestel et al., 2022). Furthermore, emerging new methodologies that combine structural and chemical imaging also offer exciting new avenues to a deeper understanding of soil systems. These correlative imaging methods use image registration techniques to combine 3D tomographic data sets with biochemical microscopic data of different modalities and scales (e.g. light, fluorescence and electron microscopy and secondary ion mass spectrometry) (Schlüter et al., 2019). This unique capability to simultaneously quantify 3D heterogenous habitat space in soil and map microbial communities and organic matter distributions are set to revolutionize our understanding of biogeochemical and physical processes in natural soil systems.

Abstract

Water in soils is only 0.0012% of Earth's water and yet it is paramount in regional scale processes, in the climate system, and for life on Earth. The storage and retention of water in soils affects energy partitioning processes at the land surface, plants transpiration, hydrological processes, and water management practices. Finally, it controls soil's ability to act as a sink or source for greenhouse gases with an indirect yet strong control on the global climate system.

Key points

- Water in soils is a small yet key fraction of the global Earth's water.
- Water in soils strongly affects hydrological, energy related, and biogeochemical processes.
- Water in soils has a large impact on human activities and on ecosystem services.
- The monitoring of soil water content provides large benefits and multiple techniques are available, each with positive and negative aspects.

Introduction

Water stored in soils is only 0.0012% of Earth's hydrosphere. Yet, the storage and retention of water in soils, its quality, and its high temporal and spatial variability is paramount in the climate system and for life on Earth in general. Such water affects regional scale processes such as the energy partitioning between latent and sensible heat fluxes at the Earth's surface, and thus air temperature, and sometimes precipitation, drought, and heat waves. The lack of soil water also constrains the ability of plants to perform photosynthesis by limiting transpiration processes and thus reducing biomass production. It directly impacts major hydrological processes such as infiltration, runoff, and groundwater recharge, as well as water management practices, such as irrigation and drainage. Finally, at longer time scales, water controls the ability of soil to act as a sink for greenhouse gases (e.g., carbon sequestration) or source (soil respiration, N emissions) thus applying an indirect yet strong control on the global climate system.

In this chapter, we first introduce water in soils within the global water cycle and then discuss regulatory features of water in soils from energy related processes to hydrology and biogeochemistry. A discussion on soil water in the context of watershed management and its impacts on ecosystem services follows. Methods for monitoring soil water content are introduced with a discussion on the issue of the spatial scale of water content in soil. Finally, several examples are described in which soil water content sensing and monitoring were combined with modelling environments.

Soil water in the global water cycle

The global amount of freshwater is generally constant and represents 3% of Earth's hydrosphere with the remaining being saline water that is mostly stored in oceans and seas, which occupy 70% of Earth's surface, or as groundwater (Aeschbach-Hertig and Gleeson, 2012; Bogen et al., 2004; Dorigo et al., 2021). However, this small percentage of freshwater is the only portion that can potentially be utilized by most terrestrial animals and by the vast majority of plants. Water contained in the unsaturated zone, which is itself a small portion of Earth's freshwater, is generally defined as water in soils.

Freshwater stored in soil as soil moisture is one of the storage pools of the water cycle, which is a conceptual model that describes and separates the processes and pathways through which the ~ 1.4 billion m^3 of Earth's water is transferred and stored. Freshwater can be found in glaciers and icecaps in its solid state, in clouds and air humidity in its gaseous state, and in lakes, streams, rivers, soils and groundwater reservoirs in its liquid state. A variety of processes such as precipitation, evaporation, transpiration, condensation, infiltration, runoff, melting, and groundwater flow can transfer freshwater from one of these storage pools to another. Water in soils represents about 0.05% of the total stock of freshwater (0.0012% of the hydrosphere) and is thus one of the smaller pools. However, especially when compared to groundwater, soil water contributes to or controls large land surface fluxes (Fig. 1). Thus, it strongly impacts terrestrial energy cycles through its influence on the energy partitioning at the surface and affects hydrological processes that are coupled to energy cycles through evapotranspiration (Bogen et al., 2004; Seneviratne et al., 2010). Finally, soil water is linked to the biogeochemical cycles of carbon and nutrients through the coupling between plant photosynthetic activity and transpiration.

Key regulatory features of water in soil

Energy related processes

Every year, approximately 5500 TW of energy, mostly from solar radiation, are used to return to the atmosphere $\sim 70,000 \text{ km}^3$ of water that is stored in Earth's soils. It is especially the water stored in the topsoil that strongly affects the energy fluxes at the land surface and thus the related meteorological and atmospheric inputs and vegetation states. Here, the net radiation that reaches the Earth's surface must be balanced by (a) fluxes of latent and sensible heat directed towards the atmosphere, (b) ground heat fluxes

Fig. 1 The global water storage pools of oceans, groundwater, ice, and other water. Of the other water pools, atmosphere, surface water, and soil water are shown together with groundwater in terms of storage and fluxes, both with values (in 10^3 km^3) and with graphical representation of their magnitude. As indicated with text citations, data from: Aeschbach-Hertig W and Gleeson T (2012) Regional strategies for the accelerating global problem of groundwater depletion. *Nature Geoscience* 5(12): 853–861; Bogen H, Hake JF and Vereecken H (2004) *Water and Sustainable Development*. Forschungszentrum Jülich; Dorigo W, Dietrich S, Aires F, Brocca L, Carter S, Cretaux JF, Dunkerley D, Enomoto H, Forsberg R and Güntner A (2021) Closing the water cycle from observations across scales: Where do we stand? *Bulletin of the American Meteorological Society* 102(10): E1897–E1935.

Fig. 2 The upper panel shows the energy related fluxes where R_n is net radiation, H is sensible heat, E_t is latent heat, G is ground heat, and S is heat stored in vegetation. The lower panel shows the hydrological processes where P is precipitation, E_t is evapotranspiration, D is infiltration, and R_s is surface runoff.

directed towards the subsurface, and (c) heat stored in the vegetation (Fig. 2). Variations in soil water content can modulate feedbacks between the land surface and the atmosphere by changing the partitioning between latent heat, sensible heat, and ground heat fluxes. Soil water availability is a limiting factor for evapotranspiration and thus latent heat, which also tightly couples the energy related and the hydrological processes (Jung et al., 2010). For example, when soil dries out, sensible heat increases, thus reducing latent heat because actual evapotranspiration falls below potential evapotranspiration. Also, the soil heat transport, and thus ground heat flux, is influenced by water movement in soil as this can redistribute heat vertically. Variations in soil water content also affect the turbulent and highly rotational air flows called eddies, the currents that transport water vapor, heat, and gaseous substances across the Earth's surface and in between surface and atmosphere. In parallel, plants covering the soil can alter heat fluxes, but such cover is strictly related to soil water availability as it will be discussed later.

Hydrologic processes

When rainfall reaches the land surface, it has a chance to infiltrate the soil. However, the infiltration rate will depend on multiple factors (Fig. 2). First, vegetation can intercept rainfall before it reaches the soil and part of this water will evaporate before doing so. The amount of interception depends on plant structure, branching, leaf geometry, and rainfall intensity, all aspects that vary considerably in time and space. When rainfall reaches the soil surface, the amount and rate at which it can infiltrate depends on rainfall intensity, vegetation type, degree of surface sealing and soil management practices (e.g., frequency and type of tillage for agricultural land). Furthermore, local factors such as the soil's hydraulic properties, initial soil water content, and the roughness of the soil surface as well as non-local terrain properties such as slope, aspect, and landscape type and location play an important role. All these vary greatly in space as different soils can be found in different areas and at different depths. For example, higher infiltration rates can be the consequence of soil heterogeneity and, especially in forest soils, of the presence of biopores and macropores. Moreover, antecedent soil saturation status can favor or reduce infiltration. A large soil water content, on one hand, can increase hydraulic conductivity, since a greater portion of pores are transmitting water, whereas on the other hand it can decrease infiltration due to the reduced suction gradient (Schumann, 1998). When precipitation rate exceeds soil infiltration capacity, water ponds on the soil surface. The ponded water can either infiltrate at a later stage, return to the atmosphere by evaporation, or generate surface runoff. Depending on the volume and energy of rainfall and runoff, erosion and transport of solutes and solids can occur. This runoff water will move towards lower elevations and, if no further infiltration or evaporation occurs, reach freshwater bodies through streams and river networks, and be eventually discharged into seas or oceans.

The water stored in soil can leave the soil profile either by the process of evapotranspiration or by drainage and leaching to groundwater or to surface waters. Evapotranspiration returns to the atmosphere about 63% of the total precipitation that reaches the land surface and consists of two major components. The first component is soil evaporation in which soil water evaporates from the soil surface. This occurs when the water vapor pressure at the evaporating surface is higher than that of the atmosphere. The water returned to the atmosphere through evaporation is purified from residuals or pollutants that remain in the soil. The second

component is the process of plant transpiration, whereby the water stored in the root zone is taken up by plants through their roots and released back into the atmosphere via the stomata in the leaves. When water availability and root extension are not a limiting factor, transpiration tends to be controlled by the available solar radiation and can be increased with the presence of wind. However, water limitation is generally a constraint to transpiration rates, especially in agriculture. In addition, plants generally cannot access all the water that is present in the rootzone, and their uptake abilities are strongly influenced by plant and soil characteristics. A paramount factor for transpiration is thus soil matric potential which represents the force that retains water in soils. In the unsaturated zone, the soil matric potential is negative and is mostly controlled by capillary forces. Plants can take up water when the soil matric potential is between the soil matric potential at field capacity and wilting point. These two values vary between vegetation types and plants varieties. When the amount of water in soil is such that the soil matric potential is larger than the soil matric potential at field capacity, soil cannot hold this water against gravity and water drains downwards and eventually reaches the groundwater.

Biogeochemical processes

Soil water affects many biogeochemical processes in soils that are related to important matter cycles such as carbon, nitrogen, phosphate, and other nutrients. It controls the reaction rates of processes, such as decomposition of organic matter and the related mineralization of organically bound N, the formation of greenhouse gases, nitrification, denitrification as well as sorption, desorption, and chemical binding of inorganic and organic compounds.

The reservoir of carbon in soils, stored both in organic and inorganic forms, is larger than that of atmosphere and terrestrial vegetation combined and is largely determined by the soil water content. Boreal soils and waterlogged peat soils in particular have great storage potential because low temperatures, oxygen levels, and pH values inhibit the decomposition of carbon in the soil. Although peatlands make only 3% of the terrestrial land surface, they store about one fifth of the soil carbon stocks. In tropical forests, high soil water content can lower the production and release into the atmosphere of carbon dioxide from the soil. In these environments, soil respiration is strongly affected by short-term soil water content dynamics and by seasonal patterns in temperature, which has a positive control on soil respiration if soil water content is not a limiting factor (Wood et al., 2013). Changes in soil carbon stock depend on input rates relative to losses and are generally slow processes. Carbon turnover is a relatively rapid process in the topsoil whereas deeper in the soil profile carbon residence times are longer. Most of the carbon inputs are plant based and as such are directly or indirectly dependent on soil water such as above- and below ground litter, root exudates, and C dissolved in the subsoil. The same applies to carbon losses through mineralization, leaching, and carbonate weathering. Furthermore, carbon can be lost via erosion and gained through deposition, which are again mediated by overland water flows.

Similar considerations can be made for nutrients such as nitrogen, phosphorus, potassium, and trace elements that have pivotal role in the support of plant growth and are a key limiting factor in most soil-vegetation ecosystems. For most of these nutrients, plant uptake is a relatively inefficient process and losses, especially agricultural products removed from the system, are difficult to balance with inputs. This is the reason why agricultural productivity is often boosted by fertilizer application practices. Water transports nutrients out of the rooting zone by either releasing them into the atmosphere via gas effluxes (e.g., NH_4 , N_2O , and N_2) or by transport through erosion, leaching, and subsurface flow that directs such nutrients into the groundwater or surface water bodies. Finally, soil water content regimes can affect soil biota which are either soil animals or micro-organisms, such as fungi, algae, and bacteria. Microbial activity is generally enhanced by high soil water availability, especially after precipitations, and bacteria in particular are influenced as their diversity is promoted by intermediate moisture conditions (Bickel and Or, 2020; Huang et al., 2021).

Water dynamics in soil, mostly due to soil heterogeneity, control the storage and transformation of anthropogenic substances that can be temporary restrained from reaching the atmosphere, surface water, or groundwater. Pollutants may originate from point-scale sources, such as industry and landfills, or from non-point sources, such as agricultural land. The recycling of such polluting materials and substances contributes to the protection of human health and is strictly dependent on the regulation of the water flow in soils where such elements are found. Thus, specific covers or barriers can be designed to limit the water flow through a waste-laden zone, with an interesting example being the artificial freezing of soil. Such measures generally provide a stable physical and chemical environment with limited releases to the surrounding biosphere though dilution, dispersion, retardation, and decay.

Soil water in the context of watershed management

Water in soils, together with other morphological and climatic aspects, such as temperature and the occurrence of seasonal soil freezing, strongly affects infiltration, groundwater recharge, baseflow, runoff, and erosion. Such variables are part of watershed management practices, which aim at managing natural resources and human needs. For example, soil water becomes key when there is a need to mitigate the adverse impacts of extremely wet or dry conditions. The amount of water that is already present in soils when precipitations occur, combined with other local and non-local variables, can lead to extreme runoff and flooding which affect human activities and natural environments. Flooding can cause soil erosion and redeposition, thus removing fertile topsoil layers on one hand and reducing water quality downstream on the other. It can also affect vegetation and reduce its contribution to interception, evapotranspiration, and seasonal patterns in water use that affect runoff and infiltration. In the prolonged absence of precipitation, drought is defined by the low availability of water in soils. Low soil water content can contribute to overgrazing or to

the spread of wildfire, thus exposing soils to erosion, especially when precipitation is renewed. On one hand, such erosion contributes to the mobilization of large stocks of organic carbon and thus to atmospheric carbon dioxide emissions. On the other hand, it diminishes soil water storage capacity and is responsible for the loss of agricultural land leading to enhanced risk of food insecurity.

Various human activities (e.g., agriculture, industry, and tourism) critically rely on the support of soil water and of freshwater in general. This has led to a conceptual subdivision between two kinds of freshwater resources, referred to as blue and green water (Falkenmark and Rockström, 2006). Blue water is stored in surface and groundwater bodies, which can be accessed to support human activities, whereas green water originates from precipitation and contributes to soil water. Green water can be either productive when it contributes to transpiration or non-productive (i.e., soil evaporation and interception). Strong interactions occur between these two kinds of water, and green water has a pivotal role in the production of biomass for human use and consumption (Fig. 3). Such importance can be exacerbated by the geographical and climatic characteristics of a given region, by human intervention, and by future climate change scenarios. When green water is not sufficient, blue water can be harvested from natural or artificial water bodies and reservoirs or can be moved from the groundwater to the surface by water-well extraction. Such water is then returned to the soil, for example in the case of irrigation. Here, an accurate and timely characterization of soil water dynamics in the root zone can enable more efficient and thus more sustainable irrigation practices. Nonetheless, only part of irrigated water will be used by crops while the remaining quantity will contribute to further evaporation, transport of solutes in the groundwater, and runoff of poor water quality. Consequently, irrigation strongly impacts soil water and soil quality. One example is soil salinization which can take place not only in irrigated land but also in areas affected by saltwater intrusion to the groundwater due to the exploitation of coastal aquifers. Another impact of irrigation practices is the increased transport of substances due to deep percolation and leaching of excess nutrients. Nonetheless, irrigation is a key solution to insufficient availability of green water and to the consequent burden for local food production, which is why some countries use more than 35% of their renewable water resources for irrigation (Faurès et al., 2002). These figures are expected to increase in the upcoming years. As such, it is paramount to balance the advantages and disadvantages of irrigation practices and increase crop water use efficiency as excessive irrigation has the potential to stress downstream ecosystems and communities by modifying the natural water cycle.

Impact of soil water on ecosystem services

As a consequence of the topics discussed in the previous sections, most of the processes related to water in soils are tightly interlinked and affect ecosystem services that are themselves related to environmental, societal, and population issues (Smith et al., 2015). This is especially true in the case of provisioning services, which are involved in the creation of physical products, and on regulating services, which are benefits obtained by the regulation of ecosystem processes (Vereecken et al., 2016).

Ecosystem provisioning services rely on soil water that regulates the production of food from plants and animals, raw materials (e.g., timber, pulp, fibers, fodder, and fertilizers), genetic resources, freshwater, energy (e.g., biofuel and wood), and ornamental resources. To a large extent, this is due to the tight relationship between water availability, plant transpiration, and photosynthesis but also to the availability of nutrients and to soil quality which are both impacted by the water in soils. Excessive water inputs can transport nutrients through erosion, leaching, and subsurface flow. Such nutrients are not only made unavailable to plants but negatively impact the water quality of ground and surface freshwater resources. Water has an impact on the ability of soils to provide

Fig. 3 Green and blue water global flows with fluxes obtained from Falkenmark et al. (2004). As indicated with text citations, data from: Falkenmark M, Rockström J and Rockström J (2004) *Balancing Water for Humans and Nature: The New Approach in Ecohydrology*. Earthscan.

additional provisioning services. For example, it impacts soil consolidation and strength and thus its ability to provide physical support and viable biological habitats.

In the context of regulatory services, water in soils indirectly affects climate through the regulation of energy related processes, plant communities, and their impact on surface albedo. This can, for example, affect the occurrence of rainfall events, drought, and extreme heatwaves. Over longer time scales, by changing levels of carbon sequestration, soil serves as a key sink of greenhouse gases. Here, changes in the amount of water in soils can significantly affect carbon stocks, having strong impacts on and feedbacks to the Earth's climate system. For example, by regulating soil temperature, soil water variations can increase or decrease the rate of microbial decomposition of organic matter. In addition, large portion of land can become a high-rate source of greenhouse gases, as is the case in the rapid thawing of permafrost soils. In addition, strong precipitation events lead to the transport of dissolved carbon or of particulate organic matter. Another indirect effect on carbon stocks is the occurrence of dry and saturated conditions that affect plant activity and thus the amount and composition of litter inputs and rhizodeposition. Within this framework, the promotion of carbon stocks in soils not only has the potential to offsets greenhouse emissions but also to maintain or improve soil hydrological functions.

Representing and monitoring water in soils

Mass balance and energy transfer methods

Mass balance methods are mathematical models used to describe changes in the water that is stored in a control volume (i.e., a soil profile). These methods make use of the principle of conservation of mass, where the water inputs are equal to the outputs. One of the simplest approaches is the water balance equation:

$$\partial S = P - ET - R$$

where ∂S is the change in soil water content, P and ET are precipitation and evapotranspiration respectively, and R is runoff which can be divided in surface and groundwater runoff. Models such as the water balance generally assume that water flow is driven by gravity whereas more complex models can consider both gravity and matric potential. Such models are often coupled to a crop module, since plants can exert a strong control over water flow. The most common approach that includes matric potential to describe water movement in soil is the Richardson-Richards equation (Vereecken et al., 2016):

$$\frac{\partial \theta_w}{\partial t} = \frac{\partial}{\partial z} \left[K(h) \left(\frac{\partial h}{\partial z} - 1 \right) \right] - Q$$

Where θ_w is volumetric water content, t is time, z is the vertical coordinate, and K is the hydraulic conductivity of the soil as a function of soil matric potential h . Such function is highly non-linear and can only be approximated using numerical methods. In unsaturated conditions, both θ_w and K are related to h and can be estimated from soil hydraulic properties (e.g., soil textural information, bulk density, and organic carbon content) by using pedotransfer functions (Van Looy et al., 2017). Plant water uptake is taken into account by the Q term which represents water that is lost due to plant transpiration and is equal to (Vanderborght et al., 2021):

$$Q = \varphi(h) Q_p(z)$$

where the potential root water uptake Q_p is multiplied by a stress factor φ accounting for soil matric potential conditions. This factor φ varies between 0 and 1 with the latter representing optimal soil matric potential (and thus water availability) conditions for plant transpiration. The φ factor is calculated using threshold values of h that can vary between different plants. Generally, extreme values of 0 for φ are assumed in saturated soils (anaerobic stress) and in soils below wilting point. The Richardson-Richards equation has a long history of successful applications but is commonly restricted to one-dimensional models. In part, this is a consequence of its high computational demand, but its application also needs precise and spatially distributed soil information (e.g., soil characteristics and hydraulic properties) that can be challenging to collect. Depending on the application, a one-dimensional modelling environment that does not consider lateral flow can neglect important components of the analyzed system, one example being the study of groundwater pumping and its effects on the surrounding aquifer. Thus, catchment-scale studies and other large-scale applications often make use of relatively simpler methods that do not fully characterize θ_w and K .

Energy transfer methods, similarly to mass balance methods, also require a control volume to be defined but in this case energy is conserved. Here the following surface energy balance equation can be applied:

$$R_n = H + E_L + G + \frac{dS}{dt}$$

where the net radiation R_n is balanced by fluxes of energy out of the control volume and by changes of energy stored within the control volume. The former fluxes are represented by sensible heat (H) and latent heat (E_L) fluxes towards the atmosphere and by ground heat flux (G) towards the soil. The latter change in energy is represented by dS/dt which is the change in the heat that is stored in the system (e.g., in the vegetation). Here, the change in soil water content at the surface is due to actual evapotranspiration ET , which is related to latent heat through the latent heat of vaporization ($ET = E_L/(\lambda \rho_w)$) resulting in:

$$ET = \left(R_n - H - G - \frac{dS}{dt} \right) / (\lambda_v \rho_w)$$

where ρ_w is the density of water. Alternatively, if temperature and vapor pressure deficit at the surface (T_s and e_s) and at a certain height (T_a and e_a) are known, the actual ET can be obtained through the Bowen ratio $B = H/E_L$. Here, B can be calculated using:

$$B \approx \frac{T_s - T_a}{e_s - e_a} \quad \text{and} \quad E_L = \frac{R_n - G}{1 + B}$$

if it is assumed that the change in heat stored by the vegetation is small enough and can thus be neglected.

Measurement techniques for soil water content sensing

A wide range of measurement techniques that determine the temporal and spatial variability of soil water content have been developed in the past 50 years, as such information is essential for a large number of studies. At the point-scale, both Electromagnetic (EM) methods and tools based on thermal soil properties (heat pulse sensors) are viable measurement techniques, with the former being the most common pick. EM methods rely on the dependency of the soil dielectric permittivity on soil water content. Since the dielectric permittivity of liquid water is much higher than that of other soil components, soil water is the primary factor that governs EM wave propagation in the soil. Such methods comprise the use of time domain reflectometry (TDR), time domain transmission (TDT), and capacitance and impedance sensors. TDR and TDT sensors measure the propagation velocity of EM waves along open and closed transmission lines, respectively, whereas capacitance sensors typically determine soil water content by measuring the charge time of a capacitor (i.e., the soil-probe system) for a given voltage. Typically, capacitance sensors operate at a measurement frequency between 50 MHz and 150 MHz while TDR and TDT operate at higher frequencies. High frequencies are favorable since they result in soil water content measurements that are less influenced by the electrical conductivity and by the imaginary dielectric permittivity of the soil. The need for automated measurement systems have largely increased the number of low-cost sensors, such as those for irrigation purposes. More recently, wireless sensor network has appeared as a promising approach for soil water content monitoring over large areas and with a high temporal resolution, which is particularly useful for the observation of ecohydrological processes, for the spatial characterization of soil properties, and for the validation of remotely sensed soil water content products (Bogena et al., 2010).

At an intermediate scale, several new hydrogeophysical measurement technologies have emerged that attempt to address the need for field scale soil water content measurements (Bogena et al., 2015). Some of these are addressed in more details in other chapters that are focused on proximal and remote sensing of soil water. Cosmic-ray neutron sensing (CRNS), for example, counts secondary fast neutrons near the soil surface that are created by primary cosmic-ray particles. These fast neutrons are closely related to the root zone soil water content within a horizontal footprint of about 200 m. Alternatively, the Global Navigation Satellite System Reflectometry (GNSS-R) signal can be used to infer soil water content since it is affected by the soil permittivity, and thus soil water, at the land surface within a radius of 50 m. Another promising approach is the use of permanently installed gamma-ray intensity monitoring stations. Here, the attenuation of gamma radiation originated from the decay of radioactive isotopes in the soil can be sensed within a horizontal footprint of 25 m approximately. Finally, non-invasive geophysical methods such as Electromagnetic Induction (EMI), Ground penetrating Radar (GPR) and Electrical Resistivity (ER) can be used to detect and study soil water content dynamics alongside water salinity, soil textural properties, and porosity among other properties. EMI induces a secondary magnetic field in the ground through the emission of a primary magnetic field and uses it to measure the apparent electrical conductivity of the soil. In GPR, an EM wave is propagated in the subsurface and its reflections are sensed at the soil surface to measure soil permittivity or electrical conductivity. ER provides information on the resistivity distribution of the subsurface which can be used to monitor soil water dynamic processes over time and space (e.g., through ER tomography).

At the regional to global scale, satellite-based sensors such as the Soil Moisture and Ocean Salinity (SMOS), Soil Moisture Active and Passive (SMAP), and Advanced Scatterometer (ASCAT) are used to monitor soil water content with a temporal resolution of a few days. However, such products have a rather coarse resolution of tens of kilometers. Higher resolution data can be obtained by synthetic aperture radars (SAR) such as the European Space Agency's Sentinel-1 and Japan Aerospace Exploration Agency's ALOS-2, alas with lower temporal resolution. In the next decade, several new perspectives are envisaged with the upcoming SAR missions NISAR (NASA ISRO Synthetic Aperture Radar), ROSE-L (Radar Observing System for Europe at L-band), and the BIOMASS mission operating at longer wavelengths. Additionally, an emerging technique for measuring soil water content from space is based on GNSS-R technology onboard small satellites (e.g., Cyclone GNSS) that provides good spatial and temporal resolution (<5 km, sub-daily) at low cost.

Alongside soil water content, another fundamental variable is soil water potential, which drives water dynamics by reflecting the energy state of water in the porous soil. Despite its paramount importance, measurements of soil water potential has not experienced the same fast-paced development found in soil water content measurements (Durner and Or, 2006). The main reasons being the need for hydraulic contact between the measuring instrument and the surrounding soil, and the lack of a measurement technique that can measure across a wide soil water content range. The selection of a particular instrumentation will thus depend on the range of interest of each given application. The most common instruments are tensiometers, which are effective between $\sim 10^{-1}$ and $\sim 10^2$ kPa (high soil water content) and are thus suited for the investigations of relatively rapid processes such as solutes transport to the groundwater. The concept behind tensiometers is long-known and several improvements were made to increase the

match between the true soil state and the tensiometer reading (advanced tensiometers) or to reduce the necessity for continuous maintenance (self-filling tensiometers). However, tensiometers generally require skilled operators, are strongly affected by soil temperature in ways that are challenging to correct, and have a limited measurement range. For example, they are generally unsuited for agricultural studies in which low soil water content limits plant growth. In the intermediate range, reference wettable porous media such as gypsum, fiberglass, and nylon are used to measure between $\sim 10^1$ and 10^5 kPa. In this range, the impossibility of obtaining direct measurements is resolved by measuring soil water content or water-content related properties (e.g., through heat dissipation or electromagnetic properties) in a reference material that is in hydraulic equilibrium with the surrounding soil. Generally, factory calibration allows the retrieval of soil water potential from soil water content. Such instruments consist of porous materials that have a wide range of pore sizes. Blocks of gypsum with embedded electrodes have been used for more than 80 years and, more recently, sensors made of gypsum wafers embedded in a granular matrix have become available. Finally, thermocouple psychrometers measurements are used in the range between $\sim 10^5$ and 10^8 kPa (very low soil water content). But their measurement range and their high susceptibility to thermal gradients makes them unsuited for the use at shallow soil depths.

Soil water and the issue of scales

Soil water content measurements cover a broad range of scales due to the numerous available sensing techniques and their fundamental differences. There is often an additional difference between measurements and modelling, which requires a change of scale between measurements and predictions. To simplify this issue, a scale triplet that applies to both measurements and models was proposed by Western and Blöschl (1999). Here, three components: spacing, extent, and support, are needed to uniquely specify the dimensions in space of a measurement or a model. Spacing is the distance between samples or elements of a model, extent is the spatial coverage (e.g., length of a transect or length of a model domain), and support is the volume of influence of a measurement or the size of a model element. Fig. 4 shows the support (black lines) and extent (colored area) of a set of measurement techniques. It is apparent how overlaps and gaps between measurements often occur, which is why the simultaneous use of different techniques is both promising and challenging. It is thus imperative to establish a framework where information from measurements and modelling predictions are optimally combined at various spatial scales and within different disciplines (Vereecken et al., 2008).

An appropriate combination of multi-scale measurements and modelling of soil water can provide large benefits to the rapidly expanding establishment of terrestrial observatories. These are research instruments composed of geographically distributed infrastructures from different fields of research that are networked through real-time, state-of-the-art communication technology (Bogena et al., 2006). The focus is the observation of terrestrial systems, which consist of subsurface, land surface (including biosphere), lower atmosphere, and anthroposphere. As shown in Fig. 4, systems are hierarchically organized along evolving scales and structures with hydrological units representing the basic scaling units. Even though terrestrial systems are extremely complex, most process-based climate and biosphere models generally provide a simplified representation of the terrestrial component. Terrestrial observatories could help remedy such deficiency and contribute to the validation and development of novel model concepts as well as methods for upscaling parameters, fluxes, and state variables. They could also provide information on interactions between the soil-vegetation and atmosphere, on the impact of land use and climate change, and on the effects of human interventions. Finally, terrestrial observatories represent a key added value to the validation and development of integrated approaches that can measure and model soil water across different scales, thus bridging key gaps in hydrological and terrestrial sciences.

Examples of the combination of soil water measurements and modelling

The value of soil water content information

The increasing use of nondestructive and remote sensing techniques to measure and monitor soil water content has resulted in an unprecedented and still growing data availability across a range of scales. An improved spatial and temporal characterization of soil water content brings a number of scientific benefits in hydrology for which Vereecken et al. (2008) offered a thorough review. Overall, the authors conclude that a unified concept for multiscale observation and interpretation of soil water content data is needed but the hydrologic community somehow lacks behind other disciplines in this regard. For this, the implementation of multiscale monitoring sites such as terrestrial observatories and appropriate databases are needed to validate upscaling theories and catchment scale models.

What benefits result from the acquisition of soil water content data? Data assimilation is for example used to improve model predictions of water fluxes and to estimate vadose zone properties. Key methods are direct insertion, statistical correction assimilation, Newtonian nudging, inverse modeling, variational approaches, linear regression equations, and sequential data assimilation methods, also known as Kalman filtering (KF) techniques. Of the latter, standard KF is the most prominent and general estimator for systems where linear dynamics are the dominant governing factor. Unfortunately, the dynamics of interest are in this case not linear, which motivates the use of extended KF and, more recently, ensemble KF which avoids many of the problems of the former filter by implementing a Monte Carlo method. The relative ease of implementation and computational efficiency make ensemble KF a very attractive option in vadose zone hydrology.

Near surface soil water content measurements have also been used to improve the retrieval of the spatiotemporal variability of water storage in the root zone and within the soil profile. In doing this, several issues should be considered such as (a) the

Fig. 4 On the left side, hierarchy of evolving scales from the point scale to the regional basin scale and relative measurement techniques and upscaling from Bogaen et al. (2004). On the right side, support and extent scales of soil moisture measurements and observations from Vereecken et al. (2008). Here, ground-based sensors are soil moisture probes (e.g., capacitance probes and TDR), geophysical methods (GPR and EMI), and radiometers (e.g., ELBARA); wireless sensor networks are soil moisture probes (e.g., capacitance probes); airborne sensors are SAR (e.g., E-SAR) and radiometers (e.g., ESTAR, PBMR, PALS); and spaceborne sensors are SAR/ScanSAR (e.g., ERS1-2, RADARSAT, ENVISAT, JERS, and ALOS), radiometers (e.g., SMMR, AMSR-E, and SMOS), and scatterometer (e.g., ERS1-2 and METOP). Was modified from data and figures From: (i) Bogaen H, Hake JF, and Vereecken H (2004) Water and Sustainable Development. Forschungszentrum Jülich. and (ii) Vereecken H, Huisman J, Bogaen H, Vanderborght J, Vrugt J and Hopmans J (2008) On the value of soil moisture measurements in vadose zone hydrology: A review. Water Resources Research 44(4).

requirement of a mathematical model that incorporates root water uptake, (b) an a priori knowledge of initial soil water content, and (c) a correct specification of hydraulic parameters. A priori information on soil hydraulic properties can be obtained using pedotransfer functions as direct measurements are rarely available. Additional state variables (e.g., temperature, leaf area index (LAI), water table depth) are needed to improve estimations. A further limitation is the eventual lack of correlation between the soil water content at the surface and in the subsurface, which can be overcome by coupling surface and subsurface soil water content. Finally, the accuracy of the input data affects the accuracy of the output with field-based measurements techniques showing strong accuracy and thus a useful addition to satellite-based measurements.

Soil hydraulic properties at the column scale are often estimated from flux measurements (e.g., evaporation and outflow) within an inverse modelling framework. In contrast, applications at the field-scale are scarce and showed that additional information (e.g., soil matric potential, soil structural characteristics, and measured hydraulic properties) and homogeneous soil assumptions are

required to constrain parameter estimation. Recently, an increase in computational power, novel optimization methods, the availability of remotely sensed soil water content and heat fluxes, and geophysical measurements has generated new opportunities for the estimation of hydraulic properties at the field to catchment scale.

Hydrological fluxes can be estimated from the spatiotemporal characterization of soil water content by using a hydrological model that is as complex as the system being studied. For example, there is a long tradition in estimating bare soil evaporation from surface soil water content. Furthermore, remotely sensed data are used to characterize soil water fluxes although this approach is generally limited to the shallow topsoil. A promising combination of remote sensing and ground-based methods (e.g., geophysical measurements) might bridge this gap in the upcoming years and provide additional benefits, for example in the prediction of the groundwater recharge. Applications to further fluxes such as runoff are still under debate, although it is known that soil water content patterns can strongly influence runoff generation. Similarly, the integration of a mechanistic based approach of root water uptake in the Richardson-Richards equation is challenging as it requires information about the soil root architecture, parameterization, and its development in time. For surface energy fluxes, it is known that the quality of regional-scale climate and weather simulations might be diminished by neglecting small-scale soil water content variability. However, not all studies corroborated such scenario, especially when soil water content is rather homogeneous in space due to, for example, soil drying.

The importance of soil water content and its spatial variability in respect to crop productivity and carbon fluxes

In the following studies, measurements of soil water content and related parameters were combined with the agroecosystem model AgroC to study water content dynamics and their effects on local water scarcity, crop performance, and carbon fluxes at the Selhausen test site near the Jülich Research Centre (Germany). The following examples are focused on the year 2016, which had hydroclimatic conditions close to the 30-year average. Thus, the importance of such research could be enhanced in years with more extreme drought conditions. The AgroC model couples (a) the SOILCO2 module for vertical water, heat, and CO₂ fluxes, (b) the RothC module for turnover of organic carbon, and (c) the SUCROS module for simulating crop growth and organic matter accumulation. Here, SOILCO2 solves the one-dimensional Richardson-Richards equation while, in SUCROS, the potential root water uptake is reduced by a stress factor φ that depends on fixed dry or wet soil conditions.

A series of 81 spatially distributed AgroC simulations were performed over an area of $\sim 1 \times 1$ km comprising five crops: sugar beet, silage maize, potato, winter barely, and winter wheat (Brogi et al., 2020). Information on soil hydraulic properties for 18 soil types were retrieved from a geophysics-based soil mapping product (Brogi et al., 2019). Simulations of soil water content dynamics were compared with measurements to corroborate the robustness of the soil description. For this, atmospheric forcing was provided by a climate station located within the study area. The simulations allowed the reconstruction of spatial and temporal patterns of leaf area index (LAI) for the five crops across the studied area, which were successfully compared with RapidEye satellite images captured throughout the growing season. The reduction of LAI and associated yield loss differed across the study area. Lower LAI and yields were found on soil-crop combinations where available water was limited by unfavorable soil characteristics, high demand from the crops, and low precipitation (Fig. 5A and B). By using this method, precise maps of simulated yield dependence on water availability were produced, which outperformed the use of commonly-available soil representations (Brogi et al., 2021). Such maps are relevant in the support of agricultural decision-making for crop type and variety selection, precision irrigation and fertilizer application, seeding date selection, and crop rotation.

A 2.8 ha sugar beet field located within the same 1×1 km study area was investigated (Herbst et al., 2021). Measurements of soil water content, net ecosystem exchange (NEE) from both point-scale chamber and field-scale eddy covariance (EC) methods, soil respiration, soil temperature, and crop physiology were carried out. These were combined with the AgroC model to simulate and understand the within-field patterns of CO₂ fluxes linked to soil water availability, soil characteristics, and state variables. During dry periods with low soil water content, the NEE measured at 18 locations with the chamber method was generally in agreement with the EC measurements but showed strong within-field variability. These 18 points were thus divided in two clusters based on the underlying soil characteristics that impacted soil water availability, and which were inferred from geophysical measurements and direct soil sampling. Simulations and measurements showed that limited soil water and the resulting reduction in root water uptake were the main driver of the spatiotemporal variability in crop growth and CO₂ fluxes. Here, the cluster with the stronger water limitation had consistently smaller biomass growth, greater soil respiration, and lower magnitude of NEE (Fig. 5C and D). This study showed how combined EC and point scale measurements can characterize complex within-field patterns in NEE related to soil water availability and how agroecosystem modelling can be used for the gap-filling of NEE measurements during drought periods. It also showed that patterns in carbon fluxes related to soil water content dynamics can be successfully measured and simulated at the field and sub-field scale, which could be of interest for future assessments of the carbon footprint of agricultural practices.

On the use of soil water content data at different scales

A variety of examples, where information on soil water content was used across scales in model evaluation, data assimilation, or refinement of coarse products can be found in literature. At a relatively small hillslope-scale, Gebler et al. (2019) combined land surface-subsurface modelling with data assimilation of soil water content on a 38 ha grassland test site in Rollesbroich (Germany). High-resolution soil water content was obtained from a dense sensor network with 61 locations and three depths (5, 20, and 50 cm). The ensemble KF was used to assimilate such measurements within the Terrestrial System Modelling Platform (TerrSysMP)

Fig. 5 Location and outline of the 1×1 km Selhausen test site (North Rhine-Westphalia, Germany) with (A) satellite-derived leaf area index (LAI) and LAI simulated with AgroC at the 9th of June 2016, (B) yield map for silage maize for the 2016 growing season, (C) apparent electrical conductivity (ECa) map of a selected 2.8 ha field with the locations of 18 point-scale net ecosystem exchange (NEE) measurements and their ranked mean relative differences, and (D) hourly eddy covariance (EC) measurements of NEE and AgroC simulations of points p2 (average soil moisture) and p16 (low soil moisture). Was modified from data and figures from: (i) Brogi C, Huisman J, Herbst M, Weihermüller L, Klosterhalfen A, Montzka C, Reichenau T and Vereecken H (2020) Simulation of spatial variability in crop leaf area index and yield using agroecosystem modeling and geophysics-based quantitative soil information. *Vadose Zone Journal* 19: e20009 and (ii) Herbst M, Pohlig P, Graf A, Weihermüller L, Schmidt M, Vanderborght J and Vereecken H (2021) Quantification of water stress induced within-field variability of carbon dioxide fluxes in a sugar beet stand. *Agricultural and Forest Meteorology* 297: 108242.

coupled to the Parallel Data Assimilation Framework (PDAF) on both a real-world example and a synthetic illustration (mimicking the real-world circumstances). This study showed that combining data assimilation and high-resolution physically based models can lead to meaningful improvements in soil water content and discharge estimation at the hillslope scale. Although better results were obtained for the synthetic illustration, especially in the simulation of discharge, reduced root mean square error of soil water content predictions was obtained for the real-world example as well. The relatively poorer improvements in the real-world example were partially attributed to model structural errors, biases in prior parameterization, and site-specific effects, which highlighted the importance of the representation of local small-scale processes and of a precise geostatistical parameterization. Furthermore, it suggested that multiple data types (e.g., evapotranspiration) should be assimilated to improve model predictions.

At the intermediate catchment scale, Baatz et al. (2017) showed the benefits of assimilating soil water content data in the Community Land Model CLM4.5. Such data was provided by nine cosmic ray neutron sensors (CRNS) located within the Rur catchment (Germany). Since a CRNS device can only provide local information due to the ~ 240 m maximum footprint, the local ensemble Kalman filter (LETKF) was used to update soil water content at unmonitored locations. Estimates of soil water content were improved by joint state-parameter estimates both during the assimilation (2011–2012) and during the evaluation period (2013). When a biased soil map was used as input for the simulations, RMSE and bias improved considerably and approached those obtained by using an actual regional soil map. The benefits of the joint state-parameter updates were confirmed with additional jackknife experiments. At one level, this study shows the potential of CRNS to improve subsurface parameterization in regional land surface models, especially in areas of the globe where prior information on soil properties is limited due to the scarcity of detailed soil maps. More broadly, the advantages provided by CRNS networks highlight the potential benefits of further extending CRNS networks at the European scale, which will require further harmonization as later proposed by Bogaen et al. (2022).

At the continental scale, Naz et al. (2019) assimilated coarse resolution soil water content maps derived from the European Space Agency (ESA) Climate Change Initiative (CCI) for the period 2000–2006 with the Community Land Model (CLM3.5) integrated with the Parallel Data Assimilation Framework (PDAF). This was carried out for Europe at a high spatial resolution of

~3 km. The assimilation of satellite data provided meaningful improvements in estimates of soil water content, which improved over all the investigated regions, except Scandinavia, and provided better predictions for summer and autumn seasons compared with winter and spring seasons. This discrepancy was attributed to data gaps, and to the presence of snow and frozen soils that limited the assimilation of soil water content in the selected modelling environment. Overall, total runoff showed only marginal improvements, especially in central Europe. This study proved (a) the potential of satellite sourced soil water content data assimilation to produce improved high-resolution simulations at the continental scale and (b) the added value of long-term observation of soil water content for hydrologic simulations in climate change studies. With the recent availability of COSMO-REA6, the period was extended until 2015 using the proposed methodology and thus obtaining a reliable high-resolution long-term soil water content product (Naz et al., 2020).

Summary and outlook

The small amount of Earth's water stored in soils is key in hydrological, biogeochemical, and energy related processes as it feeds back to vegetation growth, soil and air temperature, infiltration, and carbon storage among other processes. Thus, knowledge of the temporal and spatial variability of soil water is a paramount component of multidisciplinary research as it deeply affects natural and human environments. This is especially true for regions where extreme flooding is due to rainfall exceeding the infiltration capacity of the soils or where drought events are becoming more frequent and severe. Multiple methods and techniques are available to measure, monitor, represent, and simulate water in soils and its dynamics. Such methods vary in scale and in field of application, which sometimes results in powerful combinations of multiple techniques and models but also adds several complexities. Thus, the high spatial and temporal variation of soil water content and the fact that multiple scales (from the small field-scale to global) must be considered, should direct the hydrologic community towards more unified concepts for multiscale observations, predictions, and interpretation of water in soils.

Abstract

Important aspects of the global water cycle are influenced by soil properties and processes. Vegetation-promoted soil structure and associated biopores affect rainfall partitioning into infiltration and runoff at the catchment to continental scales; soil affects water storage and its availability for plant transpiration; resistance to soil surface evaporation varies with soil properties; and rates of groundwater recharge are modified by soil properties. The influences of soil properties and processes on regional water cycle, particularly for infiltration and surface runoff, are accentuated in humid regions and decrease for drier climate. Additionally, changes in land cover and properties from disturbances (wildfire) alter the role of soils in the hydrologic cycle. Similar effects are observed following changes to land use (e.g., clear cutting, tillage). New technologies are allowing the scientific community to more precisely quantify the global water balance, and at finer spatial and temporal scales.

Key points

- Global water balance is highly dynamic, and being altered by anthropogenic disturbances.
- Water balance is influenced by soils in nuanced ways, and depending on the regional climate.
- Satellite remote sensing is significantly improving our ability to measure global water cycle components.

Global and terrestrial water cycle

Most of Earth's diversity of life resides and is supported within a thin layer of soil atop Earth's terrestrial surface. Soil represents the primary growth medium for plants for food and ecosystem functioning, a sink for—and source of—atmospheric CO₂, a home for the most biodiverse component of life, a moderator of Earth's energy balance, and finally a significant influencer of the terrestrial water cycle, at scales from soil profile to continents. Because all life forms rely on water to function, soil water fluxes and stores affect not only the pace and partitioning of hydrologic cycle components and surface energy balance, but also sustain most of Earth's biomass (Bar-On et al., 2018). Remarkably, despite the significantly smaller area of habitable terrestrial surfaces (less than half the ocean surface area), the global biomass is overwhelmingly terrestrial (Fig. 1) and is directly supported by soil water storage (and transpiration), while the total net primary productivity on land (56.4 Gt C/yr) is similar to oceans (48.5 Gt C/yr). More significant is the nearly 80 times more biomass on land than in oceans (see Fig. 1b).

Since the previous version of this encyclopedia, a greater understanding of the many roles of soil in modulating global water cycle and climatic variables has emerged, supported by ever increasing information, tools and maps for integrating spatial and temporal observations at unprecedented resolutions. The fusion of satellite remote sensing, globally harmonized soil datasets, and georeferenced analyses offer exciting new opportunities for injecting key soil processes that affect local and global water cycle. This chapter will provide a summary of current understanding and a peek into potential future research that will further sharpen our knowledge base.

Clearly, the importance of the global water cycle can be viewed through many lenses. This chapter, however, is specifically related to the influences of soils on the water cycle at different scales—but focused more on the continental and global scales—and influence of the water cycle on soil properties and processes. These relationships are being researched vigorously today by the scientific community, especially with the growth in satellite platforms being designed and launched at faster rates, and the further development of machine learning and artificial intelligence approaches that help us parameterize point-scale or meter-scale processes using ground-based and space-based measurements. Scholarly articles are being published continuously on findings related to these topics.

Fig. 1 (a) Global distribution of biomass, (b) distribution of biomass within different compartments of the biosphere. Nearly 82% of the global biomass is associated with plants; 13% bacteria; all other organisms account for the remaining 5%. (b): After Bar-On YN, Philips R, Milo R (2018) The biomass distribution on Earth. *Proceedings of the National Academy of Sciences* **115** (25): 6506–6511. doi: 10.1073/pnas.1711842115.

Fig. 2 Global distribution of lands of various aridity levels, from arid to humid and their relative area. Modified from World Atlas of Desertification (WAD) (2022) Joint Research Center, European Commission. <https://wad.jrc.ec.europa.eu/patternsaridity> (Accessed May 2022).

The global water cycle is complex, the amounts and partitioning of precipitation to different water balance components vary greatly across geographic regions. In particular, the ratio of precipitation to potential evapotranspiration that defines the aridity index (Fig. 2) (World Atlas of Desertification (WAD), 2022) determines water availability for vegetation and humans and is used often to distinguish humid from arid biomes. The amount of precipitation and its partitioning to evaporation and transpiration greatly affect surface energy balance as well. It is estimated that 20–22% of global precipitation and 14% of global evaporation is attributed to the land surface, the rest occurring over oceans. Recent advances in Earth observing platforms and computational power to fuse satellite and land measurements can now provide maps of precipitation at spatial resolution of 1 km² and temporal resolution of an hour (e.g., the CHelsea project) (Karger et al., 2021); the Global Precipitation Measurement program (National Aeronautical and Atmospheric Administration (NASA), 2022a, 2022b); ERA5-Land program (European Centre for Medium-Range Weather Forecasts (CMWRF), 2022). Following rainfall, evapotranspiration (ET) is the largest component of the annual terrestrial water cycle that is strongly modulated by soil processes (Fig. 3) (Oki and Kanae, 2006). Nearly 70% of terrestrial precipitation is sent back to the atmosphere as ET, with transpiration (T) through plants accounting for 2/3 of ET and evaporation (E) from land surfaces (including interception) accounting for the remaining 1/3 of ET. The convergence of high resolution climatic and soil information (e.g., OpenGeoHub, 2022) at the km scale, globally, opens unprecedented opportunities for improved understanding of how soil properties and processes affect rainfall partitioning and water storage and ultimately vegetation response and surface energy balance.

Fig. 3 Primary annual fluxes (numbers in arrows are times $1000 \text{ km}^3/\text{yr}$) and freshwater stores (shown in boxes) connected with the global water cycle. Modified from Oki T and Kanae S (2006) Global hydrological cycles and world water resources. *Science* **313**: 5790. doi: 10.1126/science.1128845.

The residence time of water varies depending on the “pool” in which the water enters. For example, a molecule of water remains in the atmosphere for less than a week, in the ocean for several thousand years, in soil for a year at most (unless it travels to groundwater), or in groundwater from a matter of weeks/months to millions of years (e.g., Kralik, 2015; Wang, 2020). These are the average turnover times in various compartments of the hydrosphere.

Soil mediated fluxes

Fluxes of water across the land-atmosphere interface, whether pointed upward into the atmosphere or downward into the soil, are controlled or moderated by soil properties and processes, chief among them are the soil infiltration capacity and the unsaturated hydraulic conductivity function. Both, the infiltration rate and ability of unsaturated soil to transmit water depend on soil antecedent wetness. The relations between soil wetness and these important water transport functions has been studied for decades, often parameterized and expressed using closed-form expressions (e.g., Brooks and Corey, 1964; van Genuchten, 1980) and infiltration parameters. Much like infiltration rates and downward movement of water determined by soil wetness, also surface evaporation and plant water uptake are critically dependent on the ability of soil to support capillary flow to surface evaporation, or supply the transpiration needs of plants via root water uptake. This nonlinear dependency also highlights the intrinsic ability of soil to limit water losses to the atmosphere, when hydraulic conductivity becomes limiting. This is particularly important in arid regions in which the atmospheric demand is very high (low relative humidity and high temperature and solar radiation); in effect, soil limits evaporative losses, sheltering soil water that can support sparse vegetation (Or et al., 2013).

The control exerted by soil surfaces on infiltration affect groundwater recharge and runoff generation, and subsequent lateral water flow toward streams or other surface water bodies (Maxwell and Kollet, 2008; Taylor et al., 2012). As the spatial scale increases toward global, soil properties and soil structure, particularly the presence of macropores, still exerts influence on the partitioning of precipitation into surface runoff and infiltration in Earth system models (Fatichi et al., 2020), one of the few practical ways to simulate water balance at the global scale.

Notwithstanding the importance of soil water fluxes for life itself, changes in soil water storage play a similarly important role in climate regulation. The ingredients and manifestations of the “soil moisture memory” in the climate literature (Koster and Suarez, 2001; Seneviratne et al., 2006; Seneviratne and Koster, 2012) are rooted in soil water holding capacity, and determination of plant available soil water, with specific considerations of soil type and depth and vegetation type and its rooting depths. The soil water holding capacity extends the effects of rainfall events and modulates temperature extremes. These are largely due to plant root water uptake and transpiration at plant controlled rates during intervals between rainfall events. Soil water storage and response of plants from different biomes (e.g., forests vs. grasslands) have been shown to play an important role in the occurrence (or suppression) of

Fig. 4 The partitioning of terrestrial precipitation into different components of “blue” and “green” water based on land cover and use. The irrigation and extraction of “blue” water is from groundwater only, and estimated at around 1000 km³/yr (Margat and van der Gun, 2013). Image modified from International Soil Resources Information Center (ISRIC) (2022) <https://www.isric.org/utilise/global-issues/water> (Accessed April 2022).

heat waves (Miralles et al., 2019; Aminzadeh et al., 2021). Some have advocated mitigating the onset of heatwave by expanding the use of irrigation (Thiery et al., 2020), although economic considerations and availability of water sources for such proposed climate engineering remain debatable.

Anthropogenic effects on the global water cycle—Blue and Green water

The combined effects of growing global population with its water needs and changes in climate patterns (rainfall, extreme events, and evaporation) have altered components of the natural water balance. These changes are exacerbated by massive diversion of rivers and withdrawal of surface and groundwater resources. For example, it is estimated that human “blue” water withdrawals for agricultural irrigation alone are about 2500 km³/yr globally, representing around 70% of human “blue” water use, with 50–70% of this water consumed through irrigated crop ET (Rost et al., 2008). However, not all agriculture depends on “blue” water (irrigation); nearly 80% of global croplands are rainfed, using so-called “green” water for production of 60–70% of the world’s food (5000 km³/yr). Together with the “green” water required to support pastures and grazing (20,000 km³/yr; Rockström et al., 1999), nearly 27,500 km³/yr of water support food production for humans (combining “blue” and “green” water). This amount represents 25–30% of the terrestrial annual rainfall and highlights the magnitude of human involvement in the global water cycle (Fig. 4) (International Soil Resources Information Center (ISRIC), 2022). It also emphasizes the central role of soil in these processes, as all “green” water (by definition) is extracted from stored soil water. The unequal spatial distribution of “green” and “blue” water extraction patterns reflects climatic (rainfall for storage or irrigation primarily in arid and Mediterranean or seasonal climates) and socio-economic conditions (population density, infrastructure for “blue” water extraction and irrigation systems).

Scales of measurement and modeling of soil mediated hydrologic processes

As implied above, the scales of measurement and representation of soil hydrologic processes are intimately linked with the scales of the questions being addressed. An ongoing challenge for the scientific community is matching measurements at a certain scale with theoretical frameworks and their parameters often conceived and formulated at other scales (Dooge, 1997; Or, 2019). Studies for the water balance, for example, can be applied to a hierarchy of scales ranging from a single soil profile to a field, a watershed (a few hectares to 1000s of km²), a climatic region (from 100,000s to millions of km²) or to a global scale, assuming that the experiments are appropriately conceived and implemented. These scales were defined in part because they are tactile and comprehensible to the general public and to scientists who study them, not because the physical processes are bounded by them (even though they might be).

However, other means of assessing hydrologic responses across different spatial scales are emerging with advances in Earth observing and modeling capabilities. [Fatichi et al. \(2020\)](#) recently conducted numerical experiments on the influence of soil structure on water balance at global and ecosystem scales (e.g., grasslands, shrublands, mixed forests, etc.), rather than remaining tied to strict spatial scales listed above. The motivation is that biological processes (vegetation type, root growth, creation of biopores) that influence soil structure tend to group according to climatic environmental conditions (i.e., biomes); hence, considering the processes for each biome, and by classifying land cover accordingly (using, for example, remote sensing), researchers can apply knowledge gained at point- or watershed-scales, to larger land areas with similar ecosystem characteristics, or potentially at smaller scales when different approaches are combined (e.g., [Fang et al., 2021](#)).

The combination of Earth observation platforms and advanced analytics, like machine learning and soil pedotransfer functions, can reduce errors when parameter values are measured at one scale and applied to another scale, with the goal of predicting water balance components and closing mass balance. Conceptual and numerical models that are used to represent or simulate hydrologic processes at these different scales are becoming vital tools for researchers and decision makers who are seeking to extrapolate knowledge either up or down in scale, and into the future. Changes in water balance can then be predicted as a function of changes to climate or land use, or both, which will become increasingly common.

Key soil properties

Aspects of global water budgets that are moderated by soils can be attributed to a few key physical properties, including soil texture, soil bulk density and organic matter content. Soil texture refers to the relative percentages of sand, silt and clay fractions of mineral soil, as well as those fractions larger than 2 mm in diameters, often referred to as gravel or stones. The textural components generally control the amount of water held in soils against gravity; here finer-textured soils retain more water than coarser-textured soils, especially as the soils become drier. The means that water in soils with higher clay and silt content is more available to plant roots for transpiration and potentially for soil evaporation as well. In coarse-textured, sand-rich soils, water drains more readily (downward toward groundwater or laterally toward springs) and may no longer be available to exchange back into the atmosphere through ET processes. Soil structure refers to the arrangement of soil particles into aggregates (or peds) and the formation of soil horizons after pedogenic processes lead to concentrations of salts or clay in discrete layers, or both. Soil structures can influence the water balance in soils by formation of larger pores, through which more water will flow (and at faster rates), or potentially formation of lower conductivity layers where flow rates are lower, and where water can temporarily pond, creating localized, saturated zones. These phenomena are scale-dependent, are more likely observed at local- or ecosystem-scales, but less at global scales ([Fatichi et al., 2020](#)).

Some researchers have reported that soil organic matter, with its small size and high surface area, can significantly increase the water holding capacity of soil (e.g., [Bouyoucos, 1939](#); [Ankenbauer and Loheide, 2017](#)), improving water access for plants, increasing soil evaporation, and reducing deep recharge. Other studies have indicated that water holding capacity is influenced to a limited extent ([Minasny and McBratney, 2018](#)). These studies, while somewhat conflicting, point to a need to better understand how soil carbon manifests in the water budget and then, importantly, how to apply that knowledge at scales needed to address questions. Recently, [Bagnall et al. \(2022\)](#) highlighted the benefit of incorporating organic carbon levels into pedotransfer functions that could yield soil hydraulic properties (e.g., soil water retention and hydraulic conductivity functions) which govern soil water budgets. Another approach for incorporating emergent properties (e.g., soil structure is the so-called geo-transfer functions (GTFs)) ([Gupta et al., 2022a, 2022b](#)). GTFs expand the range of covariates considered for estimating soil hydraulic properties to include climatic, land cover, and geomorphic features, which all play critical roles in soil formation, and hence near surface water balance. The expansion of covariates beyond soil-dependent variables used for classical PTF have proven transformative in capturing nuances such as the type of clay in tropical regions ([Lehmann et al., 2021](#)) and aspects of soil structure that are correlated with precipitation, temperature and vegetation cover.

Measurement and modeling of soil water at continental to global scale

Measurements used to assess water balance are more often applied at the smaller end of the spatial scales, generally from point to regional scale, with most settling on watershed scales to capture the irregular boundaries of watersheds that contain surface water within it. At this scale, even for larger watersheds, uncertainty and error in surface water measurements are reduced, in part because the headwaters are fully contained in the region of interest and outfall is a point in space. Starting around 2015, various space agencies have designed, launched and operated satellite systems capable of estimating soil water content, from which this water pool can be quantified. Sensors on these satellite systems use radar and the dielectric response of ground surface as the surrogate indicator for soil water content. Two examples of systems used by the global Earth science community include the Soil Moisture Active Passive (SMAP) system ([Entekhabi et al., 2010](#)), operated by the Jet Propulsion Laboratory at NASA, and the Soil Moisture and Ocean Salinity (SMOS) system ([Kerr et al., 2010](#)), operated by the European Space Agency. Other systems producing soil water data products include ASCAT ([Bartalis et al., 2007](#)) and AMSR-2 ([Kim et al., 2015](#)), and when combined, several systems are able to provide water content at higher-than-designed spatiotemporal resolution, thereby coming closer to matching capabilities of these systems with the needs of the scientific communities ([Peng et al., 2021](#)).

In addition to new technology developed for interrogating surface properties at the global scale, the derivative benefits from digital innovation are equally important. For example, with the combination of more point-scale measurement systems being deployed globally, these disparate datasets can be harmonized and integrated into global or continental scale databases of water content (e.g., Dorigo et al., 2011, 2013), and soil hydraulic properties [e.g., POLARIS (Chaney et al., 2019); SoilGrids250 (Hengl et al., 2017)]. The advent of high performance computing and advanced analytics is providing the opportunity for the scientific community to estimate pools of soil water, surface water and ocean water at increasingly higher spatiotemporal resolutions, now approaching 1 km and lower (e.g., Fang et al., 2021). These new products potentially overcome technical issues in forecasting soil water at both the localized, single-grid and the regional river basin scales.

The increased spatial resolution of rainfall and soil information permits derivation of new soil-water related maps of plant available soil water or the average moisture conditions experienced by soil biota over climatic time scales. For example, a map of the so-called “climatic water content” (Bickel and Or, 2020) (Fig. 5) has been instrumental in explaining drivers for biome-scale soil bacterial diversity (Bickel and Or, 2020), enabled delineation of global earthworm distribution (whose activity is critically dependent on soil hydromechanical conditions) (Ruiz et al., 2021; see also chapter on Bioturbation). Other global climatic soil moisture data bases are now available, such as reported in Sugmin and Orth (2021) and Muñoz-Sabater et al. (2021) (ERA5-Land). The synthesis of spatially (and temporally) resolved rainfall record with soil information and hydraulic parameters provides new insights into how much plant available soil water can be stored in different soils. While the median is about 160 mm water per 1000 mm soil profile (about 22,000 km³ globally), this quantity varies widely with soil type (primarily texture and structure). Moreover, under certain climatic conditions the profile is rarely replenished to its potential, especially in hyper-arid regions, whereas in other, more humid climates the soil profile may remain close to field capacity the entire year.

Conclusions and outlook

Soil processes exert a dominant influence on the water cycle, outside of precipitation itself. While the influence is recognized at the local and watershed scales, new research is highlighting that soil processes also influence the water cycle at continental and global scales as well, though the scientific community has only begun to study the ramifications fully. Fatichi et al. (2020) showed through models that soil structure in the form of biopores (or other large preferential flow pathways) can influence surface runoff and deep percolation, hence reducing the role of ET, primarily in humid and vegetated regions. Following Fatichi’s work, Bonetti et al. (2021) proposed a framework for incorporating these structures into soil pedotransfer functions that can more easily be used in models at any chosen scale. Tashie et al. (2021) used machine learning and streamflow recession curves to constrain soil hydraulic properties used in models at the catchment or larger scales, with a goal of eventually reaching continental scale. Cosh et al. (2021), recognizing the value of point-scale monitoring, but at the continental scale, advocate for creating a coordinated network of networks, from which the scientific community and public could gain greater value. These efforts are showing the need to understand how water is partitioned into components of infiltration and surface runoff, and then again into groundwater recharge, plant transpiration and soil evaporation, all of which effect groundwater sustainability and ecosystem functions. Over the last 3–4 decades, the development, deployment and harmonizing of advanced remote sensing technology, point-scale sensing equipment, and the computational strength to process this information have significantly increased our overall understanding of the water cycle.

The rapid advances in technology and the changing community perspective toward asking globally-relevant questions provides new opportunities for placing the influence of soils on the water cycle in proper context. For example, several overriding questions that relate to the water cycle and the influences of soil are top-of-mind in the water and soil community. These include: How can we

Fig. 5 Climatic water content representing the estimated soil water content averaged over 36 years of satellite and reanalyzed precipitation record, considering soil type (field capacity) and rainfall amounts and interval (internal drainage and evaporation). See Bickel S and Or D (2020) Soil bacterial diversity mediated by microscale aqueous-phase processes across biomes. *Nature Communications* 11: 1–9 for detail.

correctly understand ET rates and processes and the influence of soil properties and processes on them at spatio-temporal scales of interest, especially at the continental and global scales? To what extent can we track the plant-available soil water as a means of understanding impacts of climate change on global vegetation? And, how will ecosystem functions and services change in different types of land covers in very wet and dry conditions (e.g., after floods or droughts) that are predicted from weather extremes. Answers to these questions require ongoing efforts and research.

Given the availability of monitoring systems for groundwater levels (but not always for withdrawal); surface water levels in rivers, lakes and oceans; and precipitation, it should be clear that uncertainty in, and availability of, soil water content and storage at the continental and global scales are still significant areas requiring improvement. So, what areas of research and understanding are needed now? Two areas are probably being pursued the most. First, remote sensing methods have continued to advance in sophistication, providing data at higher and higher resolution, with more frequent return periods, and shorter latencies between overpass and data availability. Fang et al. (2021), for example, report on a workflow that provides water content data across the continental U.S. at a spatial resolution of 400 m, though it does require combining output from several different sources (satellites and point-scale data) to validate. Future technological development of newer satellites (e.g., the NASA-ISRO SAR mission, satellite is scheduled to launch in 2023–2024) (National Aeronautical and Atmospheric Administration (NASA), 2022a, 2022b) would monitor Earth's surface at around 200 m resolution. Coupled with harmonized soil water content data, collected with accurate point-scale sensors at regional scales, machine learning approaches can be more effectively used to quickly and more accurately generate gridded water content data. Future technological development coupled with advanced analytical and computational approaches can improve our understanding of how soil processes affect the water balance at global scales. Second, the development of new maps of soil and landscape properties, developed using different types of transfer functions with or without machine learning, are needed. For example, if climate change leads to persistent drought conditions and reduced availability of soil water for plants, wholesale changes in ecosystem characteristics and services could occur, but our understanding of the volume of plant available water in soil is difficult—in part because of the large scale of measurement and in part because the soil characteristics are not parameterized in a way that facilitates analyses. Gupta et al. (2022a, 2022b) recently reported on a framework for mapping plant available soil water at the global scale, making better use of available datasets of soil parameters, and showed that they could quantify soil water residing between field capacity and wilting point. From this information, and with knowledge of local and regional climate, more accurate estimates of ET rates can be ascertained (Bickel and Or, 2020, 2021).

Abstract

Evaporation of water emitted from soil surfaces is a key process of the hydrologic cycle and the surface energy balance. It can be limited by the solar energy to vaporize water, the amount of precipitation, the soil hydraulic properties and surface characteristics (albedo, roughness, and presence of residues). Evaporation rates are large for wet soil surfaces with high atmospheric demand (controlled by energy, vapor pressure deficit, and wind velocity) but become very small when the vapor is emitted below the surface and must diffuse through a dry soil layer.

Key points

- Evaporation links the hydrologic cycle with the surface energy balance
- Evaporation stages can be classified by comparison with potential evaporation rate and by the position of the evaporation plane
- In stage-1 evaporation, capillary flow pathways connect the drying soil surface with the wet subsurface
- The length of capillary flow paths depends on soil hydraulic properties and atmospheric conditions
- Soil structures and heterogeneities have large effects on capillary flow paths and evaporation rate
- The quantification of evaporation rate can be measured with various techniques at different scales

Introduction

Evaporation of water from bare soil is an important pathway in the hydrologic cycle to move water in its liquid state back to the atmosphere as vapor. Because the corresponding phase change from liquid to gas requires a large amount of energy, the evaporation process is a key factor in both the hydrologic cycle and Earth surface energy balance. Evaporation is a relatively slow process (compared to soil water flow during heavy rainfall and ground water fluctuations) but it is very dynamic, with evaporation rates changing with time as controlled by soil properties and atmospheric conditions (see examples in Fig. 1). The key to understand evaporation rate dynamics is the quantification of water distribution at the surface and down the soil profile. In terrestrial systems, vapor is emitted from soil (soil evaporation) and from plant leaves (transpiration). After rainfall events, vapor can also evaporate from water intercepted by plant cover. The combination of these processes is denoted as evapotranspiration. In this chapter, the focus is on evaporation from the soil surface.

Fig. 1 Examples of evaporation dynamics from natural soils in field (a) and lab experiments (b and c). The evaporation rate depends on the atmospheric conditions and the soil properties. (a) The evaporation rate E (red) from a clay loam (Idso et al., 1974) is reduced during the cool night and for dry surfaces, indicated by increasing surface albedo α (shown in blue); the gray bar marks the concurrent change of E and α during the second day. (b) The response of evaporation losses on hot and windy atmospheric conditions (large rate) depends on the soil type (Jalota and Prihar, 1986) with greater fluxes for fine textured silt loam soil. (c) As already shown by Buckingham (1907), evaporation losses do not always increase with the atmospheric demand (the soil surface and air flow were warmer under ‘arid’ compared to ‘humid’ conditions): for conditions with a shallow water table, the unsaturated flow is limiting in case of high demands and a dry surface layer evolves that greatly resists vapor transport, reducing the evaporation rate.

Evaporation process in the hydrologic cycle and surface energy balance

Evaporation is relevant to water transport from the soil to the atmosphere and the consumption of solar energy. It is an important process of the hydrologic cycle, linking soil systems with the atmosphere. Evaporation E (or evapotranspiration ET in case of plant cover) is a component of the water balance, typically formulated for a soil layer of depth L . The water balance describes the change of water storage ΔS over time interval Δt as balance of fluxes as stated in Eq. (1):

$$\Delta S = P - R - E - D \quad (1)$$

with precipitation P , surface runoff R , evaporation E and drainage to deeper soil layers D . The fluxes are expressed as water volume per soil cross sectional area and time and are typically expressed as millimeters per day for a daily water balance. A change of storage ΔS corresponds to a change of water content $\Delta \theta$ equal to $\Delta S/L$. For example, the evaporation of 10 mm water (corresponding to 10 L of water evaporated from one square meter cross section) during a sunny day from a soil layer of 0.5 m thickness corresponds to a decrease of water content of 2% (when all other fluxes in Eq. (1) are zero). At global scale, evaporation from soil accounts annually for 180 mm of 940 mm precipitation (about 20%, Oki et al., 2005).

The amount of energy required to evaporate 1 kg of water is denoted as latent heat of evaporation ℓ and is about $2.45 \cdot 10^6 \text{ J kg}^{-1}$. Applied to the previous example of 10 mm evaporation per day (equal to 10 kg m^{-2}), energy of about 30 W (Joule per second) is required per square meter. This energy comes from the sun with 325 W m^{-2} arriving at the atmosphere and 136 W m^{-2} absorbed at the surface (averaged over day and night and geographic latitudes of land cover; Wild et al., 2015). For the given example, 10% of the solar energy is used for evaporation (i.e., $30/325$). This amount agrees with global averages for terrestrial surfaces (38 W m^{-2} for evapotranspiration). Formally, the surface energy balance equals:

$$R_N = R_S(1 - \alpha) + R_L^{\downarrow} - R_L^{\uparrow} = \ell \cdot E + H + G \quad (2)$$

with net radiation R_N , short wave radiation R_S , albedo α defining the amount of reflected shortwave radiation (depending, for example, on color and surface wetness of the soil, see Fig. 1a), and incoming and outgoing longwave radiation R_L . The net radiation R_N is partitioned into the latent heat flux of evaporation $\ell \cdot E$, the sensible heat flux H to the atmosphere, and the heat flux to the soil G . Eq. (1) and (2) show that the evaporation process links the hydrologic cycle with the surface energy balance (term E is in both equations). The evaporation rate E does thus depend on the rainfall amount P and the incoming energy R_N . Accordingly, the evaporation of a system or a climatic region can be characterized with respect to the climatic factor limiting the evaporation (P in water limited or R_N in energy limited systems).

The strong coupling between the hydrologic cycle and surface energy balance makes soil evaporation sensitive to climate change and change in land use. Higher temperatures increase the evapotranspiration rate. A change in land use, such as forest clearing, affects both soil properties and energy balance (change in surface reflectance and shading). Based on analysis of satellite data for the period between 1980 and 2017, Liu et al. (2021) found a significant increase of evapotranspiration in 42% of the land surface area (and significant decrease in less than 5% of area). The main driver for this increase was a change in precipitation and potential evapotranspiration. Projections of evaporation to the future with land surface models predict an increase of evapotranspiration from 550 to 580 mm per year (5.6% increase) or 560 mm per year (2.4%) depending on the emission scenario (Pan et al., 2015). For certain vegetation covers, the predicted increase could be much greater (between 9% and 24% for different scenarios). However, the response of soil evaporation to a change in atmospheric conditions is highly non-linear, as already indicated in Fig. 1 and the predicted values depend on the level of process details implemented in the land surface models. In this chapter, these details of the evaporation process and the mechanisms controlling its dynamics are presented.

Evaporation rate dynamics

The evaporation rate cannot only be limited by atmospheric conditions but by the amount of water in the soil and at the soil surface (e.g., limitation occurs when water in deeper soil layers is not transported to the surface). To distinguish between limitations by soil properties and by atmospheric conditions, the actual evaporation rate (amount of vapor emitted from soil per surface area and time) must be compared to the potential evaporation rate (amount of water emitted from a free water surface under the same atmospheric conditions). A first evaporation stage occurs when the amount of soil water and the surface water content is not limiting, such that the actual evaporation rate is very close to the potential evaporation rate and depends on temperature (an indicator for available energy) and the vapor pressure deficit in the air. More specifically, the actual evaporation flux is determined by the vapor pressure difference (between the evaporating surface and the atmosphere) and a transport coefficient (gaseous diffusion coefficient across a thin viscous boundary layer or a turbulent eddy-diffusion coefficient at larger scale). The potential evaporation rate increases with temperature, vapor pressure difference between the surface and the atmosphere, and wind velocity. For conditions with no or only moderate wind, the evaporation rates from a free water surface or a wet soil surface are very similar (actual evaporation rate close to the potential evaporation rate). As long as the water molecules evaporating at the surface are replaced by liquid water flow from the soil interior, the surface remains wet, and the evaporation rate remains constant. Eventually, when the water supply from the soil to the surface becomes too slow, the evaporated water is not replaced, and the surface becomes very dry. The presence of a dry soil surface layer indicates that evaporation (phase change) occurs within the porous medium and the vapor molecules travel through the dry soil before they are emitted to the atmosphere. The vapor transport through a dry soil layer is small and decreases with increasing thickness of the dry soil layer. The evolution of the actual evaporation rate can thus often be classified into a first evaporation stage (stage-1) with rates close to the potential evaporation rates and a second evaporation stage with the evaporation rate decreasing with time. The classification into first and second evaporation stage is not always straightforward because the evaporation rate can drop below the potential rates for different reasons as discussed next.

First and second stage of evaporation

In contrast to a completely water covered surface, the water content of a wet soil cannot be larger than its porosity. The reduced water content compared to a free water surface (that is typically used to determine the potential evaporation rate) can affect the actual evaporation rate. At the pore scale, the vapor emitted from water filled pores is not just transported vertically across the boundary layer between soil and atmosphere but diffuses as well radially across the dry surface. This lateral spreading across a hemispherical region around the water filled pores can be described as additional transport resistance compared to the one-dimensional transport across a subviscous boundary layer (Schlünder, 1988). However, under most conditions, the distances between water filled pores are small compared to the thickness of the boundary layer (that depends on atmospheric conditions) and the additional resistance of the vapor shell is also small, compared to the one-dimensional transport across the boundary layer. The sizes of the vapor shells depend on the water content and the pore size distribution. For conditions with small vapor shells compared to the boundary layer, the actual evaporation rate can be as high as the potential rate. But for thin boundary layers (a function of wind velocity) and for large pores and large spacings between water filled pores, the vapor shell resistance becomes larger and reduces the evaporation rate considerably. For evaporation from coarse textured soils under conditions with high wind velocities, the evaporation rate drops from the very beginning and no stage with constant evaporation rate can be observed (see Fig. 2).

Fig. 2 Dynamics of evaporation rates and definition of evaporation stages. (a) The evaporation rate dynamics from a coarse sand (0.3–0.9 mm particles) changes with atmospheric conditions (high and low atmospheric demand). The arrows mark the end of stage-1 and the detachment of the evaporation plane from the surface. (b) Evaporation rates expressed as function of evaporation depth (cumulative mass loss per cross-section) for coarse and fine sand (0.1–0.6 mm). The mass loss at end of stage-1 evaporation (shaded rectangle) depends on soil texture but not on atmospheric conditions. (c) After end of stage-1, water recedes from the surface until a new evaporation front is formed at onset of stage-2 evaporation (the number 1 marks the end of stage-1, 2 the start of stage-2 evaporation). The start of stage-2 evaporation can be determined by plotting E^2 (evaporation rate E) as function of time (Brutsaert and Chen, 1995), here shown for a sand with 0.1–0.3 mm particles.

In the case of thin boundary layers or large pore sizes, the absence of a period of constant evaporation rate is caused by transport processes in the boundary layer. For fine textured media the evaporation rate can drop by a different process related to the limited water flow by capillarity from the wet subsoil to replace the water evaporated from the surface. In these fine textured soils, the pores are so small (a few microns in radius or less), that the water flow is smaller than the potential evaporation rate and the actual evaporation rate may never reach the potential evaporation rate.

There are thus three causes for decreasing evaporation rates and the lack of evaporation stages with an actual evaporation rate that equals the potential rate: (i) vapor diffusion across vapor shells in the boundary layer, (ii) liquid flow through small pores and (iii) vapor transport through a dry soil layer (see previous section). The classification of evaporation stages based on the evaporation rate alone (i.e., equal or smaller than the potential rate) does not differentiate between hydration stages of the surface (i.e., how much water is at the surface) that are important for ecohydrological processes. An alternative classification of the evaporation stages can thus be based on the hydration stage of the surface and the related question of where the phase change occurs (directly at the surface or within the porous medium). In the following, stage-1 is assigned to conditions when evaporation (phase change) occurs at the surface and stage-2 for conditions with completely dry surface layers and evaporation occurring exclusively inside the porous medium.

Evaporation planes and drying fronts

Using evaporation stage classification based on the presence of a dry soil surface layer (stage-2 evaporation); stage-1 evaporation contains all situations with water evaporating directly from the surface. To keep liquid water at the surface, evaporated water must be replaced by water flow. In the special case of a shallow ground water table, the water can be supplied sustainably from the water table without changing the water content in the profile over time. For other conditions without water supply from a reservoir, the water content in the soil layer decreases during evaporation. For a wet soil layer (water content close to saturation), the water evaporated from the surface is replaced by water from the soil below, reducing the water content in the profile. Extracting water from the soil profile corresponds to air invasion and thus increasing air content, forming an interface between the wet and the partially dry soil denoted as the drying front. During stage-1 evaporation, the drying front recedes deeper into the porous medium (replacing water evaporated at the surface) and the water content in the partially dry region above the front decreases.

In the second stage of evaporation, a second interface (in addition to the drying front) between the very dry soil surface layer (Heller, 1968) and the partially wet soil is formed. At this interface, the evaporation rate is greatest (compared to the levels below) and is denoted as secondary drying front, evaporation plane, or vaporization plane. During the second stage evaporation process, the evaporation plane recedes deeper into the soil, increasing the diffusive pathways from the evaporation plane to the surface. The increasing length that must be overcome by diffusion causes a steady decrease of the actual evaporation rate (Fig. 2c).

Mechanisms sustaining stage-1 evaporation

Sustained high evaporation rates related to the presence of liquid water at the surface requires a water supply from the subsurface to replace that evaporated from the surface. The water supply is driven by a capillary pressure difference between the wet subsurface and the drying surface. At the pore scale, the air-water interface (meniscus) is positioned at the soil surface in small pores but below the surface in larger pores that drained during the process. The capillary pressure difference between the receding water meniscus in large pores and the meniscus pinned at the surface in small pores drives water flow to the surface (Scherer, 1990). The flow capacity of the capillary pathways pumping water to the surface, defines how long the stage-1 evaporation can be sustained. This capacity depends on pore size distribution (capillary pressure difference between large and small pores), the initial water content (defining capillary pressure in largest water filled pores), and the influence of concurrent drainage (and water extraction by roots). To explain the mechanisms controlling the duration of stage-1 evaporation, a simplified situation of evaporation from a saturated homogeneous soil column without concurrent drainage is considered before the effects of more complex conditions in presence of soil structures are discussed at the end of this section. In such a simplified case, air invades the large pores and forms the drying front, separating the water saturated region from one that is partially air-filled. The capillary pressure at the drying front equals the air entry value of the porous medium. During evaporation with very negative water potential in the atmosphere, smaller pores are drained sequentially and make the surface capillary pressure more negative. The decrease of capillary pressure at the surface invokes a water flow from the drying front (where pressure stays constant at the air-entry value). This water flow can be limited by two conditions: the capillary flow paths become topologically disconnected at a critical water content or the hydraulic conductivity of the flow becomes too low to sustain the potential evaporation rate. In the next subsection, the assessment of the maximum length of these capillary pathways will be presented.

The characteristic length for stage-1 evaporation

Continuity of capillary flow paths

The length of the capillary pathways that can sustain the potential evaporation rate defines the maximum depth of the soil layer than can be drained by stage-1 evaporation. On one hand, this depends on a critical water content θ_{crit} and matric potential head h_{crit} when the capillary flow paths disconnect. These critical values can be deduced from measurements of the soil water characteristics curve (relationship between water content θ and matric potential head h). At the dry end when the water content

converges to its residual value, the water extraction by applied matric potential diminishes because it becomes controlled by the flow along adsorbed water films. As a simple estimate for the convergence toward the residual water content, the soil water retention curve can be linearized as shown in Fig. 3 for two different models of soil water characteristics with the critical pressure h_{crit} that equals to the pressure value when the linearized water saturation equals 0. The corresponding water content of the original soil water retention curve at this pressure h_{crit} is used as estimate for the critical water content θ_{crit} when capillary flow paths break-up. Note that this rule to assign a minimum matric potential value to sustain capillary flow differs from other approaches that assign much higher absolute values (150–1500 m or ∞). Conceptually, this criterion is related to the pressure and water content range that limits applicability of Richards equation with the underlying flow equation (Buckingham-Darcy) and hydraulic functions (capillary bundles with Hagen-Poiseuille flow).

Capillary forces vs. gravity

The pressure to attain the residual water content is a function of soil texture as manifested in the soil water characteristics curve. It is moderately negative (small absolute values) for coarse and more negative for fine textured media. Also, the capillary pressure at the drying front (interface between wet and partially dry soil) from where water is pumped by capillarity to the surface, can be texture dependent. The capillary pressure at the drying front equals the initial capillary pressure h_0 at the onset of evaporation or the air-entry value h_{air} for initially water saturated conditions. In the second case, it is a function of soil texture (h_{air} is typically more negative in fine textured soils). In both cases, it defines the matric potential head at the deepest level where water to be pumped to the evaporation plane at the surface is replaced by air. The maximum driving pressure difference to supply water to the surface is thus $h_{air} - h_{crit}$ (or $|h_{crit}| - |h_{air}|$ using absolute values of matric potential). This capillary pressure difference must overcome the height difference (gravitational potential) between the drying front and the surface. The maximum height difference, and thus the maximum length of the capillary flow paths, is just $h_{air} - h_{crit}$ and can be denoted as ‘gravity length’ L_G . Because the texture effect on h_{crit} is much stronger (several meters) than on the air-entry value h_{air} , the gravity length depends on soil texture and is longer in fine textured soils. Due to the stronger capillary forces, a deeper soil layer can be drained by stage-1 evaporation for finer textures (as long as hydraulic conductivity is not limiting—see next paragraph) as shown by larger stage-1 mass losses in Figs. 1b and 2b.

Capillary vs. viscous flow

The capillary pressure difference pumping water to the surface must overcome (in addition to height differences) the resistance to move the viscous liquid (water). Accordingly, there is an additional criterion to sustain stage-1 evaporation related to the rate of water supply along capillary flow paths and the corresponding viscous losses. The capillary pressure difference $h_{air} - h_{crit}$ is counteracted by both gravity and viscous flow and the maximum length of capillary flow is reduced compared to the gravity length. There are different possible approaches to account for viscous flow against gravity driven by a capillary pressure difference (see next paragraph). A simple approach to account for viscous effects can be to assign an effective hydraulic conductivity K_{eff} for the flow region between the drying front and the surface (Lehmann et al., 2008). The maximum length of capillary flow paths, that is denoted as characteristic length of evaporation L_C , equals:

$$L_C = \frac{|h_{crit}| - |h_{air}|}{1 + E_0/K_{eff}} \quad (3)$$

with stage-1 evaporation rate E_0 . The smaller the hydraulic conductivity K_{eff} , the larger the effect of viscous flow resistance and the more pronounced the length reduction compared to gravity length $L_G = |h_{crit}| - |h_{air}|$. Both the nominator and denominator of Eq. (3) depend on soil texture, with increasing values for fine textured soils (large absolute values of h_{crit} but small K_{eff} for fine

Fig. 3 Characteristic lengths of evaporation determined by (i) capillary pressure differences pumping water to the evaporating surface and (ii) the hydraulic conductivity of capillary flow paths. The range of capillary pressure differences L_G can be deduced from the soil water characteristic curve (SWC) between air-entry value h_{air} and a critical capillary pressure h_{crit} close to residual water content assigned to capillary flow cessation. The values can be determined by linearization of the SWC (van Genuchten parameterization in (a) and Brooks and Corey in (b)) with superscripts ‘c’ and ‘f’ for coarse and fine sand. The inset in (a) shows the dye distribution at end stage-1 with the drying front at depth L_G . The two capillaries in (b) represent the conceptual model of water flow from the receding meniscus in the large pore to the interface retained at the surface in the small pore. (c) Three different characteristic lengths of capillary flow paths from water table L_{WT} (Eq. 4), from the capillary fringe L_{CF} (Eq. 5) and from the drying front L_C (Eq. 3) are expressed as a function of soil texture (using the shape parameter n of the soil water characteristics curve). The three formulations differ with respect to the capillary pressure at the surface h_{surf} and the unsaturated flow across the profile.

textures). The maximum length of capillary pull to sustain evaporation rate E_0 is thus short for coarse textures because of small L_C and for fine textured media due to high values E_0/K_{eff} (see Fig. 3b). The largest characteristic length L_C can thus be found for intermediate textures (loam) due to moderately large hydraulic conductivity and capillary pressure differences.

Characteristic lengths of evaporation from shallow water tables

In systems with a shallow water table at depth L_{WT} , the evaporation rate E_0 can be sustained as long as the length of capillary paths reach the surface and the water table is replenished (Shokri and Salvucci, 2011). The existence of a relationship between maximum water table depth and sustainable evaporation rate was analyzed by Gardner (1958). Using a steady state solution and hydraulic conductivity $K(h)$ dropping exponentially with decreasing matric potential head h , the water flow can be integrated analytically along the profile and the maximum water table depth L_{WT} to sustain evaporation rate E_0 equals:

$$L_{WT} = \frac{1}{\beta} \ln \left[1 + \frac{K_s}{E_0} \right] \quad (4)$$

with saturated hydraulic conductivity K_s and the specific matric potential head $|1/\beta|$ where $K(1/\beta) = K_s/e$ (Euler number e). As shown in Fig. 3c, the length L_{WT} is larger than L_C because (i) it is considered in the derivation of Eq. (4) that the matric potential at the surface (driving the capillary flow) can go to $-\infty$ and (ii) the capillary pathways start at the free water table and not at the drying front. The mathematical procedure (and assumptions) used to develop Eq. (4) can be applied as well for the water flow from the drying front at capillary pressure h_{air} to the surface with matric potential h_{crit} . The expression for this length L_{CF} equals:

$$L_{CF} = \frac{1}{\beta} \ln \left[\frac{E_0 + K_s \exp(-\beta|h_{air}|)}{E_0 + K_s \exp(-\beta|h_{crit}|)} \right]. \quad (5)$$

Note that the thickness of the saturated region above a water table is denoted as the capillary fringe. Like the drying front for evaporation of saturated soils, the top of the capillary fringe is an interface between saturated and unsaturated conditions with matric potential head h_b . Eq. (5) thus corresponds to the length of flow paths from the capillary fringe (CF) to the surface as denoted by index CF. As shown in Fig. 3c, the lengths L_{CF} and L_C are very similar for coarse textured soils but differ for finer textures due to the different description of the unsaturated flow across the profile.

Characteristic length and stage-2 evaporation

The characteristic length of evaporation (defining the thickness of soil layer that can be drained by stage-1 evaporation) is relevant as well for stage-2 when the evaporation plane is below the surface. Two situations with respect to the evaporation plane below the surface must be distinguished. For evaporation from a shallow water table, the maximum length L_{WT} increases with decreasing evaporation rate E_0 . For an evaporation plane below the surface at depth z , the vapor must be transported across a dry soil layer by gas diffusion at a rate $E_z < E_0$. If the capillary flow is fast enough to sustain E_z (but too small to sustain E_0), the evaporation plane stays at a depth z below the surface. Without a shallow water table, the evaporation plane recedes deeper into the soil during stage-2 evaporation with a rate controlled by vapor diffusion (see next paragraph). Because the evaporation rate from the receding interface is reduced by diffusion through the dry layer, the viscous losses are reduced as well and the length of capillary flow paths from the wet subsurface to the receding evaporation plane, as determined by Eq. (3), becomes longer compared to the value computed with E_0 .

Stage-2 evaporation and diffusion across a dry soil layer

The presence of a dry surface layer reduces the evaporation rate very effectively by slow vapor diffusion from the receding evaporation plane to the surface across the tortuous diffusive pathways. The evaporation rate is determined by Fick's law of diffusion and depends on the diffusion coefficient in the dry soil D_s , the pressure difference between the vapor pressure at the evaporation plane (C_{sat} , considering saturated vapor pressure) and in the atmosphere C_{atm} , and the length of the diffusive pathways, i.e., the thickness of the dry soil layer. Because the Fickian flux is inversely proportional to the thickness of the dry layer, the evaporation rate drops continuously with the retreat of the evaporation plane. But the change from relatively constant stage-1 evaporation rates to smaller and decreasing stage-2 evaporation rates (following the Fickian law) is not instantaneous but occurs during a transition period. Experimental results based on dye deposition patterns (the deposited dye marks the position of the evaporation front) suggest that the evaporation plane during this transition period does not move gradually from the surface but 'jumps' to a depth ξ (Shokri and Or, 2011). Once the liquid is detached from the surface, a new evaporation front is formed at a depth ξ that is remarkably independent of soil texture and is about 10 mm. After the formation of the new evaporation front, it recedes then more gradually into the soil as function of time given by:

$$E(t) = D_s \cdot \frac{(C_{sat} - C_{atm})/\rho}{\sqrt{\xi^2 + t \cdot \frac{2D_s(C_{sat} - C_{atm})/\rho}{\Delta\theta}}} \quad (6)$$

with water density ρ and the water content difference $\Delta\theta$ between the wet region below the drying front and the dry layer above the vaporization plane (Or et al., 2013).

Effects of structure formation and land use on evaporation stages

The mechanisms limiting stage-1 evaporation that were explained in the previous subsections for homogeneous soils (no structures) can also be used to assess the effects of soil structure (and structure destruction) on evaporation losses. In natural soils with vegetation or large organic matter content, a surface layer with plant litter or large aggregates can be formed with small capillary forces and accordingly a short characteristic length L_c . Due to the weak capillary forces, the capillary pressure difference pumping water to the surface is small and stage-1 evaporation rate can only be sustained for a short period of time; as a result, the evaporation front recedes quickly from the surface after rainfall or irrigation. The addition of a layer with weak capillary forces can thus reduce stage-1 evaporation and evaporation losses in general as is shown in Fig. 4 for various types of surface structures. In addition to large aggregates or plant litter, crop residues can cover the surface as mulching layers (Fig. 4a). Also casts of earthworms, coarse sand layers, salt crusts (Fig. 4b) and layers of hydrophobic material (Fig. 4c) have the same suppressing effect on evaporation losses.

For the surface layers presented in Fig. 4, the evaporation losses were reduced by layering. However, depending on the capillary forces and thickness of the individual layers, layering can result in prolongation of the stage-1 evaporation process. This occurs when a fine textured material is on top of a coarser one and the pore sizes of the two materials intersect. This can formally be expressed as $h_{crit}^c < h_{air}^f$, with more negative critical capillary pressure in the coarse material h_{crit}^c than the air entry value in the fine material h_{air}^f (with superscripts c and f for coarse and fine material, respectively). In that case, an enhanced capillary pressure difference of $h_{air}^c - h_{crit}^f$ (compared to $h_{air}^c - h_{crit}^c$ in the case of homogeneous coarse material) drives the water supply to the surface. This situation corresponds to the compaction of the surface layer, increasing the capillary pull to the evaporation plane at the surface. Note that for layering with increasing pore sizes from top to bottom, the typical water content profile (water content increasing with depth) can be inversed, with the wetter layer on top of the drying layer (Goldberg et al., 2021). Structure formation and cultivation of land can also generate other structures than aggregates and layers. Freezing and thawing, burrowing activities of animals, wind erosion and compaction along wheel tracks can result in a vertical arrangement of materials with contrasting properties. The parallel arrangement of fine (strong capillary forces) and coarse textured materials (weak capillary forces) results in preferential air invasion and drying front formation in coarse material, pumping water to the fine material that can remain saturated. Later in the process, the evaporation plane in the coarse textured region starts to recede with the evaporation plane in the fine material still pinned at the surface. The duration of stage-1 evaporation (presence of hydraulically connected water at the surface) can be extended compared to homogeneous material due to the enhanced capillary pressure difference between the air-entry value h_{air}^c of the coarse material and the critical matric potential value in the fine h_{crit}^f . An example of enhanced water losses from a laboratory experiment is shown in Fig. 4c.

In addition to heterogeneities within the soil, the roughness of the surface can affect the evaporation rate as well. Surface roughness increases the surface area (compared to a flat surface), and wind and radiation induce a complex pattern of the boundary layer thickness and vapor concentrations along the surface (controlling the local evaporation rates and the viscous losses to transport water to the drying surface). Depending on the details of roughness geometry, atmospheric conditions, and hydraulic soil properties, the evaporation ratio from rough to smooth surfaces can vary considerably (Vanderborght et al., 2017).

Fig. 4 Experimental results on the role of surface layers and structure formation on evaporation losses. The evaporation rate E is cumulated with time to compare the evaporation loss from a heterogeneous soil ('structure'; solid line) to a homogeneous soil ('control'; dashed line). (a) Covering the surface with straw (red; Bond and Willis, 1969) or corn stover (blue; Klocke et al., 2009) affects surface energy balance and capillary flow to the surface. (b) Adding surface layers with low capillary forces stop water supply to the surface: casts of earthworms on silt loam (blue; Ma et al., 2020), a coarse sand layer on top of sandy loam (red; Chen et al., 2020), and a salt crust of a sandy soil (inset; Zhang et al., 2013). Note that the red line shows a field experiment in cold season in a desert with low evaporation rate. (c) Lab experiments with coarse sand with a hydrophobic layer fixing evaporation plane below the surface in red (Shokri et al., 2008) and the vertical arrangement of sand layers increasing the capillary pull in blue.

Quantification of the evaporation process at different scales

Pore scale considerations

The evaporation stage transition as described in the previous sections depends on pore sizes and liquid phase continuity that can be quantified using three-dimensional imaging and simulations with pore networks (Nasir et al., 2022). In contrast to the conceptual picture of capillary bundles (as implemented in the hydraulic functions to model evaporation at larger scale), measurements and modeling reveal that water does not only flow in saturated small ‘pipes’ but along crevices and particle contacts (Tuller and Or, 2001). The dynamics of the liquid configuration in corners and its effect on evaporation rate can be studied in singular capillaries with angular cross-section, or in microfluid networks with well-defined geometries obtained with various etching techniques (Ding and Geistlinger, 2021). Despite the idealized geometry used in microfluid networks, such systems show the dominant role of liquid pinned in corners to sustain stage-1 evaporation rates. As long as continuous structures of liquid pinned in corners exist, water will flow to the surface along a capillary pressure difference and sustain stage-1 evaporation rate.

Imaging at the column scale

The combination of standard laboratory experiments (monitoring mass balance and point measurements of water content and matric potential head) with imaging methods offers a possibility to quantify evaporation rates and water content (and temperature) profiles simultaneously. Measuring the mass loss by soil evaporation and comparing it with the measured potential evaporation rates (e.g., from a water-filled column) gives information about the evaporation stage (constant or decreasing). The simultaneous imaging of dye deposition that is added in small concentrations to the water (for example, Brilliant Blue) enables the monitoring of the first and second drying front. The transition to stage-2 evaporation is marked by the onset of dye deposition below the surface (starting at a depth ζ around 10 mm as explained previously). More advanced imaging techniques (using X-ray, nuclear magnetic resonance, or neutron imaging) can delineate the evolution of the soil moisture profile during the process. Evaporation stages can also be characterized by thermal imagery of the surface, linking the evaporation rate with temperature patterns (temperature is cooler in wet regions with high evaporation rates; Nachshon et al., 2011).

Note that the evaporation process at the column scale can also be used to measure the unsaturated hydraulic conductivity and the soil water characteristics curve by simultaneous measurements of water content and matric potential gradients induced by evaporation (Schindler et al., 2010).

Processes at the field scale

In contrast to experiments under laboratory conditions, the boundary conditions in the field are more irregular with diurnal and seasonal cycles (see Fig. 1a). In addition to the temporal variations at the field scale, the spatial heterogeneities can be much larger and more irregular compared to lab experiments. The mass balance (and thus the evaporation rate) cannot be deduced from point sensors due to such heterogeneities (i.e., point measurements are not representative). To measure the water balance (and evaporation rate) under field conditions, weighable (micro-)lysimeters can be used. In contrast to micro-lysimeters that can be filled non-destructively (size in the order of 0.1 m), larger lysimeters with diameters at meter scale are typically re-packed and installed at a lysimeter station to ensure proper maintenance and instrumentation (an exception is the lysimeter network SOILCan with large soil monoliths taken non-destructively in the field and transported to the lysimeter station; Pütz et al., 2016). Evaporation from lysimeters is determined by measurements of the other terms of the mass balance equation (drainage, change in water storage, precipitation, and runoff; see Eq. (1)). Complementary to the actual evaporation rate, the potential evaporation rate can be measured from the water level in an evaporation pan (for example, Class A evaporation pan). Lysimeter networks (TERENO-SOILCan (Pütz et al., 2016) and SOPHOS (Chief et al., 2009)) allow observation of changes in water and energy balance during climate change and with different covers (e.g., bare soil or different types of plants). An alternative approach to the quantification of evaporation by measuring weight change of lysimeters, is the measurement of vapor fluxes in the atmosphere using the eddy-covariance method. The method requires the simultaneous measurement of wind speed (using a sonic anemometer) and vapor concentration (infrared gas analyzer) to determine the upwards directed evaporation fluxes. Depending on the height of the eddy covariance measurement (instruments can be installed on a high tower), the dimensions of the footprint of the measurements (i.e., the area that contributes to measured fluxes) can be several 100 m (Chu et al., 2021). This method is thus appropriate to measure evaporation at larger scales as discussed next.

From catchments to global analyses

The evaporation losses of catchments can be deduced from long-term averages, such that the water storage term (ΔS) in Eq. (1) becomes small and evaporation can be estimated as difference between precipitation P and river discharge $R + D$ (Graf et al., 2014). For high eddy covariance towers (see previous paragraph), the measurements average the evaporation rate over large areas and can be used as well to assess the water balance of slopes and small catchments. A global network of Eddy-covariance measurement sites (<https://fluxnet.org/>) provides data to quantify the mechanisms controlling evaporation rates in different climatic regions. From a global point of view, FLUXNET data provide a sparse point pattern of evaporation data and the gaps between must be filled with satellite-based approaches and modeling. Remote sensing from satellites enables mapping of key factors controlling the evaporation

Fig. 5 Characteristics of bare soil evaporation at global scale. (a) Evaporation rate as function of water content for three different soil textures (Eq. 7). The evaporation rate is limited by the transport resistance through the unsaturated soil and the atmospheric boundary layer. (b) Simulated actual evaporation E and potential evaporation rate E_0 scaled by precipitation amount P for different climatic regions. A fraction of precipitated water is lost by leakage to deeper soil layers. The presence of plant cover in non-arid regions reduces the soil evaporation by transpiration, water interception and shading. (c) Global map of soil evaporation (without evaporation of water intercepted from plant cover) averaged over 36 years period computed with daily time steps and spatial resolution of $1/4^\circ$. (d) Soil texture information is used to (i) estimate the thickness of the soil layer contributing to stage-1 information and (ii) to compute the texture dependent evaporation rate shown in (a).

fluxes. Measurements in the infrared range of the spectrum provide information on temperature and in microwave range on air humidity (Holmes, 2019). Typically, the potential evaporation rate is deduced from temperature and relative humidity measurements and the actual evaporation rate is then expressed as a function of the potential rate using modeling concepts of various complexities. Some estimates of actual evaporation do not rely on soil information but estimate the actual rate as a function of temperature dependent vapor pressure deficit and relative humidity (Mu et al., 2011). More complex models estimate the actual evaporation rate as a function of modeled water content (Miralles et al., 2011). The relationship between evaporation rate and water content depends on soil texture (see Fig. 5a) and is related to the flow resistance through the unsaturated soil surface layer (Merlin et al., 2016; Lehmann et al., 2018). The evaporation rate from the soil surface depends on both (i) transport resistance of viscous flow in the soil and (ii) gas diffusion across the atmospheric boundary layer, and can formally be expressed as function of water content θ :

$$E(\theta) = \frac{E_0 \cdot K_{eff}(\theta)}{E_0 + K_{eff}(\theta)} \quad (7)$$

with potential evaporation rate E_0 and the effective hydraulic conductivity K_{eff} of the soil layer. The effective hydraulic conductivity can be estimated as $K_{eff} \sim 4K(\theta_{surf})$ with the water content at the surface θ_{surf} (Haghighi et al., 2013). Another effect of soil texture on evaporation rate dynamics is the texture-dependent thickness of the soil layer that contributes to stage-1 evaporation (see Fig. 3c). To model these textural effects on evaporation at the global scale, maps of soil texture of unprecedented resolution can be used (www.isric.org/explore/soilgrids, www.openlandmap.org). The water content controlling the actual evaporation rate is calculated for soil profiles consisting of a few soil layers using bucket models or solving the Richards equation. In the example shown in Fig. 5, the evaporation was calculated at global scale for a soil texture dependent layer thickness as defined by the characteristic length L_C in Eq. (3), defining the soil layer contributing actively to stage-1 evaporation (Or and Lehmann, 2019).

To compare evaporation dynamics from different catchments and regions, the evaporation rate E is plotted in Fig. 5b against the potential evaporation rate E_0 , both values scaled by the precipitation P . The figure shows the separation of regions with different climate and different soil properties. The amount of evaporation can be limited by energy (potential rate E_0 is smaller than precipitation P), water (potential rate E_0 is larger than precipitation P) but also depends on the soil hydraulic properties and the length of capillary flow paths pulling water to the evaporating surface. Note that the comparison of actual vs. potential fluxes scaled by the precipitation P is a common diagnostic tool for the analysis of evapotranspiration, i.e., the sum of transpiration, soil evaporation and evaporation of water intercepted by plant leaves (Budyko analysis; Liu et al., 2021).

Summary

The vapor transport from terrestrial systems to the atmosphere consumes globally about 60% and 25% of incoming water and energy fluxes, respectively. Notwithstanding that about 70% of global evapotranspiration can be assigned to transpiration (Paschalis et al., 2018), the evaporation from soils discussed in this chapter is a key process of the hydrologic cycle and the surface energy balance. The evaporation rate changes in time with (i) atmospheric conditions (available energy, vapor pressure deficit in the

atmosphere, wind and surface properties) and (ii) the available water in the soil. With respect to the amount of soil water, not the mere amount in the profile but the capacity to bring soil water to the evaporating surface determines if the actual evaporation rate can meet the atmospheric demand. This capacity is defined by the hydraulic conductivity and the capillary pressure difference between the wet subsoil and the drying soil surface. It depends on the length of capillary flow paths sustaining the surface evaporation rate imposed by the atmospheric conditions. This length changes with soil texture and imposed rate. The disconnection of the capillary flow paths results in the retreat of the evaporation plane from the surface and the formation of a dry soil layer. The presence of a dry layer reduces the evaporation rate that is now controlled by vapor diffusion across the dry soil layer from the receding evaporation plane.

Abstract

Evapotranspiration is the second largest hydrological flux over land, which is also the linkage between the energy, water and carbon cycles. Here I review the definition, concept development and quantification of evapotranspiration. Merits and limitations of mathematical evapotranspiration models are discussed. The magnitude of evapotranspiration and its components are summarized, the responses of evapotranspiration to global environmental changes and the use of evapotranspiration information for water management are also briefly discussed.

Key points

- Evapotranspiration is a fundamental linkage between Earth's water, carbon and energy cycles.
- State-of-the-art evapotranspiration models often fail to represent the feedback between internal processes of evapotranspiration.
- Evapotranspiration estimates agree reasonably well among existing studies while quantifications of evapotranspiration components still contain large uncertainties.
- Responses of evapotranspiration to climate and land use/cover changes and the consequent impacts on the climate system are important future research directions.

Introduction

Evapotranspiration represents the process of water phase transition from liquid to gas form and then transfer into the atmosphere. Evapotranspiration may occur from the Earth's surface (e.g., the soil or a water body), through plant leaves (termed transpiration) or from rainfall intercepted by objects above ground (primarily vegetation in natural environments). The term evapotranspiration (ET) combines these three components, though interception is not explicitly mentioned in the compound term. Among different processes within the terrestrial hydrological cycle, land surface evapotranspiration plays an important role in determining the global water balance and linking the global water, energy and carbon cycles. On the one hand, ET moves a vast amount of water vapor upwards into the atmosphere and supports land surface precipitation. On the other hand, ET controls land-atmosphere feedback via modulation of the surface energy budget. From a water balance perspective, land surface evapotranspiration is the second largest water flux (after precipitation) within the terrestrial hydrological cycle, which accounts for about 65% of land surface rainfall (Oki and Kanae, 2006). This ratio can be even exceed 90% in arid regions (Budyko, 1974). Like other hydrological fluxes, evapotranspiration is commonly expressed in terms of depth per time, and common units of mm day^{-1} . When spatially integrated over an area (m^2 , such as a field, catchment, basin or country), the dimensions of evapotranspiration become volume per time, and common units are $\text{m}^3 \text{day}^{-1}$ or GI day^{-1} . In addition, because the phase change of water from liquid to gas is associated with the increase in internal energy, the latent heat of vaporization (2257 J g^{-1}) is usually used to convert the units of evapotranspiration into its energy equivalent (i.e., latent heat flux, usually in W m^{-2}).

Historical development of the concept

The formal appearance of the term “evapotranspiration” in the scientific literature was firstly made by an American geographer and climatologist, Charles Thornthwaite, who used the term “potential evapotranspiration” for climate classification (Thornthwaite, 1948). In contrast to actual evapotranspiration that occurs under real surface conditions, potential evapotranspiration defines the rate of evapotranspiration that would occur over surfaces with an (often hypothetical) unlimited supply of water.

Regardless of evapotranspiration or potential evapotranspiration, the term “evapotranspiration” itself has been refuted by a number of scientists in the field, e.g., Howard Penman, John Monteith, Charles Priestley and more recently by Miralles et al. (2020), Monteith (1986) and Penman (1948), on basis that it was clumpy and unnecessary, because the three components of “evapotranspiration” essentially share the same physical processes and the term “evaporation” was equally valid for the total water loss via vaporization and its components. Historically, the term “evaporation” was first documented in the sixteenth century (and later by Dalton, 1802) and also covered the water loss from plants.

Despite all the objections, however, the use of “evapotranspiration” has been embraced and become increasingly popular over recent decades. One possible reason is perhaps to emphasize the physiological controls on transpiration that is indeed different from a purely physical process of water loss from water/soil/wet canopy surfaces and to highlight the role of vegetation in controlling the terrestrial hydrological cycle that was overlooked at one time. The term “evapotranspiration” has also been commonly adopted by ecologists and agricultural scientists to stress the simultaneous control of plant stoma on transpiration and photosynthesis processes.

Measurement of evapotranspiration

Among all components within the hydrological cycle, ET is invisible and arguably the most difficult one to be accurately quantified. Field measurements of ET are generally classified into two groups: mass balance methods and micrometeorological methods. The mass balance methods use evaporation pans and weighing lysimeters to directly measure mass loss attributed to ET. An evaporation pan is used to determine the evaporation rate from open water surfaces under the prevailing climatic conditions. With proper implementation and calibration, pan evaporation is often considered a standard measure of potential ET. However, as evaporation pan is often too small to exert influence on the above atmosphere, the rate of evaporation recorded by evaporation pans are not necessarily equivalent to that would be measured over extensive wet surfaces as required in the definition of potential ET, if the surrounding surfaces are water-stressed. For such cases, Brutsaert (2015) introduced a term called “apparent potential evaporation” to reflect the difference.

Weighing lysimeter is another mass balance-based equipment for direct ET measurement and is often considered to be the most reliable approach of quantifying ET with the highest accuracy, yet still subject to local calibrations. Various kinds of weighing lysimeters are developed for specific purposes, ranging from cup-size micro-lysimeters, which measure soil evaporation beneath vegetation canopies or between plants, to large-scale lysimeters that ensure sufficient area and depth to support mature forest and trees growing in them. Other field methods instrument a soil profile with water content sensors to resolve other components of the water balance other than ET (similar to a lysimeter under field conditions).

Measurement of ET using micrometeorological methods includes the energy balance Bowen ratio system and the eddy-covariance system. The energy balance Bowen ratio system quantifies ET from observations of net radiation, ground heat fluxes and the vertical gradients of temperature and humidity at two fixed heights, with an assumption that the transfer coefficients of heat and water vapor are the same within the near-surface boundary layer. The eddy-covariance system measures sensible and latent heat flux through statistical covariance between the heat and moisture variation and vertical velocity using rapid responses sensors at frequencies typically equal to or greater than 10 Hz. With specific gas analyzers, the eddy-covariance system can also be used to measure exchanges of other tracer gases (e.g., CO₂, CH₄) between the land and the atmosphere. Due to its sound physical basis and fast technology advancements over the past three decades, the eddy-covariance system is now widely recognized as the best method to directly measure ET (and other tracer gases) at the ecosystem scale and is widely accepted in many important boundary layer experiments, in particular FLUXNET (Baldocchi et al., 2001). However, one unsolved issue with the eddy-covariance system is it often suffers from the energy balance non-closure problem, i.e., the sum of sensible and latent heat fluxes measured with eddy-covariance is often less than net radiation minus ground heat flux measured concurrently. There also remain difficulties in applying the method over tall, heterogeneous canopies, sloping surfaces, and when atmospheric conditions change rapidly (Monteith and Unsworth, 2013).

There are also methods for directly measuring the three ET components. Besides micro-lysimeter that measures evaporation from soil surfaces as mentioned above, the sap flow technique is designed to measure whole-plant transpiration using heat as a tracer of sap flow movement within a plant. The difficulty is then to upscale transpiration from a single tree to the entire ecosystem of interest. Canopy interception water loss can be quantified as the difference between rainfall recorded above and below vegetation canopies.

Models for evapotranspiration

Although field-based measurements are generally more reliable and accurate in quantifying ET, they are often costly and require substantial efforts in their installations and maintenances. Additionally, these field-based measurements can only provide ET

measures at the site level and often over limited periods. Consequently, mathematical models are important tools for estimating ET at varying spatial and temporal scales.

Numerous factors can affect the ET processes, including the meteorological conditions, surface moisture status, vegetation coverage, plant physiological characteristics and soil hydraulic attributes (Stanhill, 2005; Lehmann et al., 2018), so existing ET models are highly diverse in their structures and complexities depending on whether and how these factors are represented in the models. Earlier developments of ET models are made in two parallel pathways: the aerodynamic approach (Dalton, 1802; Sutton, 1934; Taylor, 1922) and the energy balance approach (Bowen, 1926; Brunt, 1939; Cummings and Richardson, 1927). The aerodynamic approach (also known as the bulk formula) estimates ET from vapor pressure gradients and a transfer coefficient determined from the wind profile, whereas the energy balance approach calculates ET using estimates of both net radiation (R_n) and the Bowen ratio (the ratio of sensible to latent heat flux). Although both methods are physically-based and theoretically sound, they had been rarely used in practical ET estimations in the early years, mainly due to the lack of surface temperature (T_s) measurements. In aerodynamic approaches, the surface temperature was needed to quantify the saturated vapor pressure at the evaporating surface, while in energy balance studies T_s was needed to estimate the net radiation and the Bowen ratio.

In 1948, Howard Penman reconciled the radiative and aerodynamic aspects of evaporation and provided a so-called combination approach for evaporation prediction (Penman, 1948). The major innovation of Penman was to eliminate surface temperature T_s via the assumption of saturated vapor pressure at the evaporating surface and linear interpolation of the air temperature from a reference height above the evaporating surface (e.g. 2 m above the surface), at which air temperature and vapor pressure were conventionally measured. As only standard meteorological data were needed, the Penman model was soon adopted by hydrologists and irrigation engineers and the approach is still widely used in the fields of hydrology, agriculture and micrometeorology.

However, although T_s is not explicitly needed in the Penman model, the Penman model still suffers from two issues regarding T_s . First, the temperature for assessing the slope of the saturated vapor pressure-temperature relationship (the Clausius-Clapeyron relations) is unknown. In practical applications, this slope is usually assessed using near-surface air temperature, but such treatment is only strictly valid if there were no temperature difference between the evaporating surface and the height at which air temperature is measured (Monteith, 1981). McColl (2020) offers a simple solution to this issue. A more difficult challenge emerges from the use of R_n as an independent forcing in the Penman model. However, R_n is always a function of T_s because T_s directly determines outgoing long-wave irradiance (via the Stefan-Boltzmann relation). One way to resolve the R_n representation problem is to assume the surface is at the air temperature and calculate the so-called isothermal net radiation. The fact that the surface is not at air temperature can then be accounted for by introducing an additional (radiative) resistance (Monteith and Unsworth, 2013). Nevertheless, these modifications to the Penman model are rarely used in current applications. At a more fundamental level, T_s is itself not independent of evaporation; instead, T_s can be seen as the consequence of a balance between surface radiative forcing and energy partitioning. In other words, neither R_n nor T_s can be considered to be truly independent of evaporation. This follows that the Penman model may be used for evaporation estimation but not for process understanding or evaporation attribution. Similar issues also exist in the model of Priestley and Taylor (1972) and others that require R_n as an input. Recently, by explicitly acknowledging the inter-dependence between radiation, surface temperature and evaporation, Yang and Roderick (2019) developed a maximum evaporation theory that circumvents the needs of R_n and T_s in estimating evaporation in a purely physically-based framework, which is a major advancement in the field and can be the basis of a new approach for evaporation estimation.

Originally, the Penman and Priestley-Taylor models were developed for evaporation from open water surfaces, hence not suitable for water-stressed conditions. In addition, stomata of plant leaves represent an additional resistance (by design) to vapor transfer between canopies and the atmosphere, which is accounted for in neither the Penman nor the Priestley-Taylor model. To account for these effects, Monteith (1965) introduced another resistance term called the surface resistance into the Penman equation and yielded a new model for ET estimation that is now widely known as the Penman-Monteith model. The difficulty of applying the Penman-Monteith model lies in the reliable determination of the surface resistance, which describes the resistance of vapor transfer from a combined soil and vegetation surface and cannot be determined independently from the first principles. It was until a large amount of ET observations became available (the value of surface resistance can then be determined by inverting the Penman-Monteith model with observed ET), which motivated the development of empirical surface resistance models (e.g., the Jarvis type models; (Jarvis, 1976)), the Penman-Monteith model had become increasingly popular in practical ET estimations. Similar approaches can also be applied to the Priestley-Taylor model by empirically reducing the Priestley-Taylor coefficient under potential conditions to reflect the environmental limitations on ET under non-potential conditions (e.g., Martens et al., 2017).

In addition to surface resistance, the Penman-Monteith type equations also require another resistance term (i.e., aerodynamic resistance) that quantifies the heat and water vapor transfer from the evaporating surface into the atmosphere, which is a function of wind speed, surface roughness and atmospheric stability. For a neutral atmosphere and a wind speed of 5 m s^{-1} (measured at 2 m height), typical values of aerodynamic resistance are 68 s m^{-1} , 45 s m^{-1} , 18 s m^{-1} and 6.5 s m^{-1} for water surfaces, grass (vegetation height = 0.1 m), agricultural crops (vegetation height = 1 m) and forest (vegetation height = 10 m), respectively (Shuttleworth, 1993).

Quantification of ET at regional or even larger scales has been rapidly advancing since satellite remote sensing data became readily available in the 1970s. In general, ET models based on remote sensing can be grouped into three types: surface energy balance (SEB) models, vegetation index (VI)—land surface temperature (T_s) space models, and Penman-Monteith-based models. An SEB model explicitly deals with sensible heat flux (based on concurrent observations of land surface temperature and near-surface air temperature) and calculates latent heat flux (or ET) as a residual in the surface energy budget equation (Yang et al., 2015). A VI— T_s space model determines the partitioning of surface available energy into sensible and latent heat fluxes based on the interpretation of the image (pixel) distribution in VI— T_s space (Carlson, 2007). Different from the SEB and VI— T_s models that rely on remotely sensed T_s , the Penman-Monteith based models do not require T_s as model input. Instead, they calculate ET

directly from the Penman-Monteith type equations in which the surface resistance is estimated based on remotely sensed VI and concurrent ground observations/satellite retrievals of meteorological conditions (Mu et al., 2007; Zhang et al., 2016). It should be noted that traditional satellites (e.g., Landsat, MODIS, AVHRR) only have moderate-to-low temporal coverages, which requires an additional temporal scaling method to upscale instantaneous ET retrievals at the satellite-overpassing time to longer time scales. This upscaling procedure often introduces additional uncertainties in the final ET estimates. Recent developments of geostationary satellites, which provide temporally continuous observations of land surface variables, represent an effective and promising way to overcome uncertainties raised by traditional upscaling methods and should be considered as a key focus in future studies.

Magnitude of evapotranspiration and its components

Considerable efforts have been made to estimate global terrestrial ET. At the global level, these estimates based on different methodologies are typically around 500 mm per year (ranging between 450 and 550 mm yr⁻¹) (Mianabadi et al., 2019; Zhang et al., 2016). However, the magnitude of ET shows a great spatial variability across global terrestrial environments (Table 1). The rate of ET is generally higher in tropical regions and gradually decreases towards both poles (Fig. 1A). At the continental scale, South America

Table 1 Evapotranspiration and its components in different Geographic regions.

Geographic region	Total ET (mm yr ⁻¹)	E_c (mm yr ⁻¹)	E_c/ET (%)	E_s (mm yr ⁻¹)	E_s/ET (%)	E_i (mm yr ⁻¹)	E_i/ET (%)

E_c : plant transpiration; E_s : soil evaporation (including snow sublimation); E_i : canopy interception water loss.

Data is taken from the GLEAM-v3.5a global ET product from 1982 to 2012 Martens B, Miralles DG, Lievens H, van der Schalie R, de Jeu RAM, Fernández-Prieto D, Beck HE, Dorigo WA and Verhoest NEC (2017) GLEAM v3: Satellite-based land evaporation and root-zone soil moisture. *Geoscientific Model Development* 10(5): 1903–1925.

Fig. 1 Global pattern of mean annual ET and its components. (A) Total ET, (B) E_c/ET , (C) E_s/ET and (D) E_i/ET . E_c : plant transpiration; E_s : the sum of evaporation from soil/open water surface and sublimation from snow surfaces; E_i : canopy interception water loss. Data is taken from the GLEAM-v 3.5a global ET product from 1982 to 2012 Martens B, Miralles DG, Lievens H, van der Schalie R, de Jeu RAM, Fernández-Prieto D, Beck HE, Dorigo WA and Verhoest NEC (2017) GLEAM v3: Satellite-based land evaporation and root-zone soil moisture. *Geoscientific Model Development* 10(5): 1903–1925.

shows a way larger mean annual ET than other continents, due to a high ET rate over Amazonia. Africa has the second largest mean annual ET that is close to the global mean value, primarily driven by a high ET rate from the Congo basin despite a low ET in the Sahara Desert. For the remaining continents, their mean annual ET are all lower than (or close to) 400 mm yr^{-1} . The magnitude of ET also shows an evident distinction between climatic aridity zones (Table 2). In global humid regions where ET is primarily controlled by energy availability, the mean annual ET is around 570 mm yr^{-1} . By contrast, in arid regions where water is the most limiting factor of ET, the mean annual ET is lower than 130 mm yr^{-1} . At the biome level, forests generally show a higher ET rate than other biome types, with the highest ET rates found in evergreen broadleaf forests (primarily tropical rainforests) and the lowest ET rates occurred in deserts (Table 3).

While the estimates of total ET in different studies show a certain degree of agreement, quantification of ET components is more difficult and their estimates diverge substantially among studies. Plant transpiration (E_c) is commonly acknowledged as the largest component of ET at the global scale, yet existing estimates of the ratio of transpiration to total ET vary greatly from less than 25% to as large as 90% (Fatichi and Pappas, 2017; Wei et al., 2017). The ratio of E_c /ET estimated from land surface models (22–58%) are generally lower than those from other methods, whereas isotope-based approaches often give the highest E_c /ET estimates (65–90%; e.g., Good et al., 2015; Jasechko et al., 2013; Wei et al., 2017). The E_c /ET ratio estimated from methods based on remote sensing is typically between 50% and 75%, which are broadly consistent with measured values across (limited) global ecosystems (50–65%) (Schlesinger and Jasechko, 2014; Wei et al., 2017). Using field observations to constrain climate model predictions, a recent study reported a global E_c /ET ratio of $62\% \pm 6\%$, which seems to be a reasonable estimate (Lian et al., 2018). Compared with E_c , the other two ET components account for much smaller proportions of total ET. Typical values of soil evaporation (E_s) estimates are about 10–25% of total ET and those of canopy interception (E_i) are 10–20% of total ET (Miralles et al., 2016; Zhang et al., 2016).

Spatially, places with a larger E_c /ET usually also show a greater E_i /ET, which are primarily distributed in forest ecosystems as well as in humid regions. An interesting phenomenon is that the humid region does not necessarily have the highest E_c /ET value, due to more interception water loss in the region, compared with sub-humid and semi-arid regions (Table 2). Arid regions have the smallest E_c /ET but the greatest E_s /ET value due to sparse vegetation coverage in the region and thus ET consists primarily of non-biological water loss. For different biomes, the greatest E_c /ET ratio is found in cropland, possibly due to artificial measures that intend to minimize non-biological water loss and thereby maximize water use efficiency in these locations. In contrast, the smallest E_c /ET occurs in deserts, where vegetation cover is sparse and the total ET is dominated by soil evaporation.

Table 2 Evapotranspiration and its components in different climatic regions.

Climatic region	Total ET (mm yr^{-1})	E_c (mm yr^{-1})	E_c /ET (%)	E_s (mm yr^{-1})	E_s /ET (%)	E_i (mm yr^{-1})	E_i /ET (%)
Arid	129	56	43	72	58	1	1

Data is taken from the GLEAM-v3.5a global ET product from 1982 to 2012 Martens B, Miralles DG, Lievens H, van der Schalie R, de Jeu RAM, Fernández-Prieto D, Beck HE, Dorigo WA and Verhoest NEC (2017) GLEAM v3: Satellite-based land evaporation and root-zone soil moisture. *Geoscientific Model Development* **10**(5): 1903–1925.

Evapotranspiration in a changing environment

Due to the intrinsic nature of ET in linking the water, carbon and energy cycles, changes in ET have been widely studied to assess the impacts of global change on the Earth system. According to the IPCC AR6 assessment report, global mean surface temperature has increased by about 1 °C in the last decade compared to the pre-industrial level (Gulev et al., 2021). Meanwhile, observations and climate model simulations report a global hydrologic sensitivity of about 2% K⁻¹ (Allen and Ingram, 2002; Boer, 1993), suggesting that the global ET has increased by ~2% since the industrial revolution. This ET increase is so much smaller than the increase in globally averaged atmospheric specific humidity that is close to the Clausius-Clapeyron value of around 7% K⁻¹. This is mainly because the increased surface temperature directly yields an increased outgoing longwave radiation so that changes in net radiation (and thus the total available energy for ET) are small (Roderick et al., 2014). The relatively low hydrologic sensitivity suggests a somewhat muted response of ET to climate warming. Nevertheless, this relatively small ET increase only applies to the global scale, at which ET mostly consists of evaporation from ocean surfaces. On land, trends in ET can be much larger yet with high spatial heterogeneity.

Elevation in atmospheric CO₂ concentration (CO₂) is the ultimate driver of anthropogenic climate warming. Besides its direct greenhouse gas effect, elevated (CO₂) also affects vegetation water use via the so-called fertilization effect. On one hand, plant stomata partially close in a higher (CO₂) environment, which leads to a higher stomatal (and thus surface) resistance and consequently a lower transpiration rate at the leaf level. Field observations reported a mean increase in leaf-level stomatal resistance of 22% for an increase in (CO₂) of 201 ppm (from 366 to 567 ppm; Ainsworth and Rogers, 2007), which is equivalent to a stomatal resistance sensitivity to changes in (CO₂) of 0.11% ppm⁻¹. This is in good agreement with climate model projections that show a mean surface resistance sensitivity to changes in (CO₂) of 0.09% ppm⁻¹ (Yang et al., 2019). Studies further showed that the reduction in ET caused by (CO₂)-induced partial stomatal closure is of a similar magnitude to the increased ET caused by warming-induced vapor pressure deficit increases in global non-water-limited regions, leaving the ET changes strictly follow that of net irradiance (Milly and Dunne, 2016; Yang et al., 2019). On the other hand, the fertilization effect of (CO₂) on vegetation increases foliage cover and plant rooting depth (Nie et al., 2013; Zhu et al., 2016). With all else held constant, increased foliage cover and plant rooting depth would result in higher water consumption (i.e., transpiration) by vegetation. Due to the opposing responses of vegetation water use to elevated (CO₂) at the leaf level and the canopy level, the sign and magnitude of the net (CO₂) impact on transpiration (and ET) still remain contentious. Field observations based on ecosystem-scale Free Air CO₂ Enrichment experiments do not show a consistent ET change (increase or decrease) under elevated (CO₂) either (Donohue et al., 2017).

Land use and land cover changes also affect terrestrial ET. Of particular interest, revegetation, as one of the most effective measures for ecosystem remediation and climate mitigation, has been carried out across the globe over the past few decades, resulting in a significant greening trend, especially in China and India (Chen et al., 2019). These extra plants consume more water, resulting in an enhanced ET in revegetated areas. Studies have been arguing that the enhanced ET caused by revegetation may lead to local water resource imbalance, as evidenced by declines in soil moisture and streamflow in revegetation regions (e.g., Feng et al., 2016). On the other hand, enhancement in ET increases local moisture supply. This, together with revegetation-induced alternations in local energy partitioning that changes the atmospheric stability within the lower boundary layer, potentially enhance local moisture recycling and hence promote the formation of more precipitation that sustains the continuity of ET increases.

Evapotranspiration for water management

Knowledge of ET is important for efficient water resources management, especially for irrigation scheduling. Prior to ET information being available, the need for irrigation was determined in several ways, for example, using visual indicators such as plant color or leaf wilting (Doorenbos and Pruitt, 1977). However, these indicators appear too late to prevent yield reduction or decline in quality. In comparison, ET directly indicates the crop water requirement, which, in combination with soil characteristics, can be used to determine not only when to irrigate but also the amount of water needed (Goyal, 2014). Consequently, adopting ET-based irrigation scheduling is also an important way of water-saving in irrigation regions by avoiding over-irrigation (e.g., flood irrigation with fixed amount) and the likely consequent soil salinity (Chhabra, 1996; Yang et al., 2012). Because of all these benefits, many methods have been proposed to determine ET for different crops and agricultural regions to guide irrigation scheduling over years, among which the “crop coefficient—reference crop ET” method recommended by FAO may be arguably the most widely acknowledged and used method in today’s irrigation scheduling practice all over the world (Allen et al., 1998). In addition to agricultural water management, information of ET has also been increasingly used in the Integrated Water and Environment Management (IWEM) at the basin scale (Mendicino and Senatore, 2012; Wu et al., 2014), since ET not only quantifies the total basin water consumption but also represents the central linkage between the water cycle and other ecosystem or environment services (e.g., agricultural production and carbon sequestration). The difference between water input (mainly precipitation) and consumption (ET) also determines the amount of environmental flow that fundamentally supports the aquatic ecosystems within the basin. Nevertheless, despite the great progress in remote sensing ET techniques over the past few decades, the precision of ET information over large spatial extents and long temporal periods still remains a key challenge to successful basin-wide IWEM practice.

Summary

As the second largest hydrological fluxes on land, evapotranspiration fundamentally links the Earth's water, carbon and energy cycles and serves as a key indicator of global change. However, the quantification of evapotranspiration, in particular its components, has long been a challenge. Field methods are costly and can only quantify evapotranspiration at a point scale and for relatively short periods, whereas mathematical models often fail in presenting the feedback between internal processes of evapotranspiration. Averaged over global terrestrial environments, plant transpiration is the largest component of total evapotranspiration, which somehow justifies the use of the combined term "evapotranspiration" such that to highlight the role of terrestrial vegetation in controlling evapotranspiration. With the ongoing climate change and intensified human activities that considerably alter land surface characteristics, the quantification of responses in evapotranspiration to these global change signals and the consequent feedbacks to the climate system are key scientific questions to be answered in future studies.

Abstract

Soil water is only partially available to plants. A wet soil quickly drains to field capacity (FC), and during further drying through evapotranspiration, water potential and hydraulic conductivity decrease, and root water uptake becomes more difficult. At some water content, the limiting point (LP), drought stress leads to transpiration reduction. When reaching the permanent wilting point (WP), root water uptake is too little for a plant to survive. The difference between FC and WP is called total available water (TAW), whereas FC minus LP represents the readily available water (RAW). As both texture and structure affect soil hydraulic properties, they can be linked to TAW and RAW. Poor soil management may negatively affect plant available water.

Introduction

Not all water in the soil can be used equally by plants. The maximum amount of water a soil can hold and make available to plants has been the subject of research of many disciplines including agronomy, soil science, climatology, hydrology, and ecology.

The availability of soil water for root water uptake is determined by rooting characteristics and soil hydraulic properties. There may be limitations caused by macroscopic or microscopic porosity. The macroscopic limitation refers to very wet conditions, in which the soil water will quickly drain through macropore flow and move below the reach of the rooting system. The microscopic limitations determine the drought stress on the dry side. Water is held by capillarity stresses within the rooting zone but can no longer be extracted by plant roots due to its low potential energy and reduced soil hydraulic conductivity.

The plant available water fraction, also referred to as *total available water* (TAW), is commonly defined as the difference between the volumetric water contents at field capacity (FC) and the permanent wilting point (WP):

$$TAW = FC - WP \quad (1)$$

The values of FC and WP are typically obtained from soil water retention characteristics, with FC ranging from -50 to -300 hPa water potential and WP corresponding to $-15,000$ hPa water potential.

Another term with a similar meaning, but with a slightly different purpose, is the *readily available water* (RAW). The lower limit of RAW is the limiting soil water content (LP). Rather than being based on water potential like WP, LP is based on the limiting hydraulic conductivity causing the onset of plant drought stress:

$$RAW = FC - LP \quad (2)$$

RAW can also be interpreted as the fraction p of TAW that can be depleted before the onset of drought stress:

$$RAW = p \cdot TAW \quad (3)$$

where p is the depletion factor, ranging between 0 and 1, and defined as

$$p = \frac{FC - LP}{FC - WP} \quad (4)$$

For a healthy plant, when the soil water content is within the RAW range, the transpiration is at its potential or sink limited level, depending exclusively on the atmospheric demand. On the other hand, below LP transpiration falls below its potential level and becomes source limited (soil resistance to the water flow is increased), meaning that the water availability is insufficient to sustain the atmospheric water demand.

The amount of available water depends not only on FC, LP, and WP, but also on rooting depth Z_r . A plant with a deeper rooting system exploits a larger volume of soil and has more water at its disposal. TAW and RAW can therefore be multiplied by Z_r to find the respective total and readily available storage capacity in length units, e.g., mm. As root depth depends greatly on plant species and phenological stage, the storage capacity is always a variable quantity. For instance, the root depth of most annual crops is less than 1 m, while deep-rooted natural plants in a forest may reach several meters. Furthermore, the role of active roots and root length density stratification in the soil profile is not included in the root depth parameter. For local scales with homogeneous cropped fields, determination of root depth may not be a critical issue. However, for catchment and regional scales, the diversity of plant species and phenological stages make root depth determination extremely challenging.

The upper limit of plant available water: Field Capacity

Field capacity (FC) is a concept originating from irrigation management and associated with the soil water content after major drainage has ceased. Although it refers to a discontinuity of the water films in soil pores, there are various interpretations based on a specified matric potential, time after thorough wetting, or minimal flow rate at the profile bottom. Usually, field capacity is determined in the laboratory after desorbing an undisturbed soil sample to a specified matric potential (often -300 or -100 hPa). Sometimes field capacity is determined in the field one or 2 days after thorough wetting of a soil, then taking soil samples for volumetric water content. Other field approaches examine matric potential using a tensiometer and measure soil water content with sensors.

Simulated water movement in soil has been used to determine when drainage is small and field capacity is reached (Meyer and Gee, 1999; Reynolds, 2018). Sometimes the modeled approaches result in unrealistically long predicted times to cessation of drainage, up to 100 or even 1000 days for soils with high clay contents. Part of the problem is ignoring the effect of soil structure and biopores or cracks, which means that soils with high clay contents can have large pores that drain fast. The main problem with modeling approaches is that they are usually determined for soil areas without plants. Field approaches are more realistic than modeled flux-based output (Chandler et al., 2017). Fig. 1 gives an example using the field procedure of Chandler et al. (2017) to determine field capacity from soil water content data. Often field-determined field capacity is wetter than laboratory-determined field capacity (De Jong Van Lier, 2017).

An important issue in interpreting FC as the upper limit for PAW is the time to reach FC associated with a negligible bottom flux. Laboratory-based approaches ignore the plant root—soil interaction in water uptake. Many field studies have shown that plants often use water from the soil wetter than the drained upper limit. Roots can extract soil water to meet the atmospheric demand even as drainage continues (De Jong Van Lier, 2017; Logsdon, 2019). Roots do not wait 2 days or more before taking up soil water unless there is aeration stress which may lower the upper limit of soil water content for plant water uptake (Letey, 1985; Da Silva and Kay, 2004).

The depth of root growth also affects plant available water provided by soils. As upper soil layers dry, plants might extend their root systems to explore deeper soil, contravening a fixed root zone. Wetter soil below the root zone results in a gradient to the drier root zone, replenishing some of what the roots have already extracted and supplying additional soil water that can be extracted by

Fig. 1 Upper soil water cutoff using the procedure of Chandler et al. (2017) for a loam and a silty clay soil. Unpublished data is from the study by Logsdon (2015) for water content 0–15 cm depth.

the roots (Logsdon, 2019). This replenishment through the soil may occur on a diurnal basis: root water extraction at day, and upward water replenishment at night (Cordeiro et al., 2015). In addition, water can move from deeper roots to shallow roots, which then release the water for later uptake, which is called hydraulic lift (Caldwell et al., 1998).

The lower limits of plant available water

Permanent wilting point

The lower limit of plant available water, the permanent wilting point (WP) was introduced at the beginning of the 20th century by Briggs and Shantz (1912). From experimental data with wheat plants, they found that the *wilting coefficient* could be accurately estimated by dividing the “moisture equivalent” (water content retained by the soil in opposition to a centrifugal force of 100 g) by the factor 1.84. Nowadays, the most common “definition” of WP is in terms of a matric potential of $-15,000$ hPa. This value is almost without exception used in models and allows accurate predictions. WP corresponds to a condition at which the soil water potential and the soil hydraulic conductivity are so low that not even a minimal amount of water can be absorbed by the root system. Although a dependence of WP on crop characteristics, soil hydraulic properties, and atmospheric conditions is to be expected, the main reason for using a fixed matric potential for WP is the experimental difficulty of its measurement, as well as the relative irrelevance of its exact determination, at least for agronomic applications (Savage et al., 1996).

An indirect method to determine wilting point is to see where soil water content levels off at the lower end, leaving residual water held in disconnected pore spaces. This requires automated soil water sensor data over wet and dry times of the season.

WP measurements directly from plants are rarely performed, but when performed usually follow the Briggs and Shantz (1912) and Taylor and Ashcroft (1972) protocol. The method consists of growing plants in small pots, with evaporation from the soil surface prevented by a seal of wax over the soil surface. After establishment of the plants, the pots are kept immersed in a water bath to avoid condensation of the soil moisture on the pot walls. The plant is allowed to grow until it wilts and then it is allowed to recover in a dark, humid chamber. If it recovers, the procedure is repeated. If the plant does not recover in 24 h, the corresponding soil water content is considered to be the WP.

Limiting hydraulic conditions

Whereas WP defines a water content that is so low that plant growth and survival is no longer possible, transpiration will be initially limited when soils are wetter. This limiting water content is sometimes referred to as “trigger point” in irrigation management, or as limiting or critical water content (LP) in soil physics. It is the lower limit of readily available water (RAW), corresponding to the water content at which the overall hydraulic resistance of the pathway between soil and leaf becomes limiting to the transpiration rate. Consequently, at LP crop transpiration turns from its sink-limited value in the constant rate phase (determined by atmospheric properties like vapor pressure deficit, wind speed, temperature, and incoming radiation) into a source (=soil) limited value in the falling rate phase. The source-limited rate is primarily determined by soil, root, and xylem hydraulic properties. In particular, the soil hydraulic conductivity is highly dependent on soil water content and matric potential.

The correct determination of LP is important to agronomic (irrigation) management, as well as for hydrological modeling. It is more important than WP because soil water content reaches values below the limiting water content much more frequently than wilting point. A process-based determination of LP requires a full hydraulic parameterization of the soil-plant-atmosphere pathway (Cowan, 1965), and relies on numerical solutions requiring detailed information on hydraulic retentivity and conductivity, root system geometry, and root and xylem hydraulics (Javaux et al., 2013; De Jong Van Lier et al., 2013).

For applications requiring a less detailed approach, simple (piecewise linear) models have been proposed to describe the relative transpiration T_a/T_p as a function of water content, normally including FC, LP, and WP as threshold values. A commonly applied model of this type is the transpiration reduction function used in the model Aquacrop (Fig. 2).

In the FAO methodology, LP is defined as a function of FC and WP and a depletion factor p according to

$$LP = WP + (1 - p)(FC - WP) \quad (5)$$

Values for p are given by Doorenbos et al. (1986) for four crop groups with decreasing sensitivity to drought. Values of p vary between 0.125 and 0.875 as a function of the atmospheric demand expressed as potential transpiration.

Unlike water content, matric potential and its gradient can be linked directly to soil water movement and root water extraction. Therefore, it makes more sense to express threshold values of soil water availability (FC, LP, and WP) in terms of water potential. The widely used reduction function proposed by Feddes et al. (1978) is included in important hydrological models like Hydrus (Šimůnek et al., 2016) and SWAP (Kroes et al., 2017). It describes the root water uptake (RWU) reduction factor α as a piecewise linear function of matric potential (Fig. 3). Factor α is defined as

$$\alpha = \frac{S_a}{S_p} \Leftrightarrow S_a = \alpha S_p \quad (6)$$

where S_p ($\text{m}^3 \text{m}^{-3} \text{d}^{-1}$) and S_a ($\text{m}^3 \text{m}^{-3} \text{d}^{-1}$) are the potential and actual root water uptake rate, respectively. The resulting transpiration rate is obtained by integrating S_a over the rooting zone. This integration can be performed using weighting factors,

Fig. 2 The transpiration reduction function used in Aquacrop / FAO, defining relative transpiration T_a/T_p as a function of water contents FC, LP and WP, showing Total Available Water (TAW) and Readily Available Water (RAW).

Fig. 3 The Feddes reduction function, defining the RWU reduction factor α as a function of matric potential, showing the five phases of RWU.

usually the root length density. Matric potential h_3 delimits the constant and falling rate phase and corresponds to LP, with values between -100 and -1000 hPa depending on crop species, according to [Taylor and Ashcroft \(1972\)](#).

The measurement of LP or h_3 is based on the determination of the water content at the onset of relative transpiration $T_a/T_p < 1$ (Figs. 2 and 3). By evaluating different plant species, phenological stages, soil types, and atmospheric conditions, we may determine how LP depends on these factors. Usually, plants are allowed to establish in pots in greenhouse experiments until a predefined development stage. At this point, the pots are split into two groups, one continuing to be watered, the other one without a water supply. Evaporation is minimized by sealing the soil surface with wax or a layer of coarse sand, and pots are weighed daily to determine the soil water content and the average transpiration rate. The transpiration rate of the irrigated plants is taken as potential transpiration T_p , while the transpiration rate of the non-irrigated plants is the actual transpiration T_a . A daily evaluation of the relative transpiration T_a/T_p allows finding when $T_a/T_p < 1$, the transition from the constant to the falling phase (Figs. 2 and 3), corresponding to LP. The accuracy of the determination depends on the homogeneity of soil characteristics (physical, chemical, and biological), root proliferation, and leaf area in both treatments (irrigated and non-irrigated). As LP depends on atmospheric conditions, similar atmospheric condition around the onset of $T_a/T_p < 1$ also makes the determination of LP more accurate.

Other limitations to plant water availability

In addition to the limits of plant available water related to soil hydraulic properties, as discussed above, other physical limitations to the access of plants to soil water may be present. In particular, those limitations caused by reduced aeration in wet soil or by too high a penetration resistance for plant roots in the dry soil have been considered. An attempt to integrate these limiting factors of different nature into one indicator was proposed by [Letey \(1985\)](#). The resulting Least Limiting Water Range (LLWR) is constrained at the wet side by drainage (FC) or aeration requirements, whereas the dry side may be controlled by hydraulic properties (WP) or mechanical limitations to root growth.

Plant available water: The role of soil texture and structure

Plant available water and soil texture

Plant available water is defined by FC and WP, and both can be assessed by a matric potential. The combination with existing pedotransfer functions based on soil texture (sand, silt, and clay content) allows predictions of plant available water for different texture classes. Fig. 4 shows an example of the relation between texture class and FC, WP, and available water. The vertical distance between FC and WP equals the plant available water. In this example, it is largest for (silt) loam texture. It should be remembered that soil hydraulic properties like FC and WP are not only determined by texture, but also by structure. Therefore, Fig. 4 may give a rough indication but cannot be used to assess plant available water in any soil and under any circumstances.

Plant available water and soil structure: The role of soil management

Together with soil texture, soil structure determines soil hydraulic properties. In its turn, soil structure is determined by pedogenetic factors in the long term, and by soil management in the short term. Soil management may affect soil structure in many ways. The most important processes regarding plant available water are compaction and loosening.

Compaction is caused by heavy machinery and results in the reduction of total soil porosity, but mainly macroporosity. It usually affects the surface layer of a soil, impacting the infiltrability, rootability, aeration, and water redistribution. Compaction has a negative impact on soil quality and plant growth, but its direct impact on plant available water is less straightforward.

The loosening and mixing of surface soil is one objective of tillage. Although tillage effects on soil structure can be of short duration, the mixing and aeration of carbon-rich topsoil will lead to enhanced oxidation of organic matter, causing a reduction of soil carbon content. Humic substances are important in stabilizing soil structure; hence the loss of organic C may lead to a deterioration of soil structure, with consequences for plant available water too. The mismanagement of organic C may thus lead to compaction and a decrease of plant available water.

The use of plant available water

Use of TAW and RAW in irrigation management

The limiting soil water content LP defines the onset of drought stress, and as such it is essential for the proper optimization of irrigation decisions based on the soil water content status. As mentioned, for irrigation purposes the depletion threshold p is an empirical factor that ranges between 0 and 1, and it is listed for crop groups and specific atmospheric water demands, e.g., in the FAO irrigation guidelines. According to these guidelines, p together with FC and WP determines LP (Eq. 5). However, LP represents the limiting soil hydraulic conditions, therefore, its proper estimation should consider soil hydraulic properties (retention and conductivity), root density distribution, and the atmospheric water demand. The correct determination of upper and lower limits of TAW and RAW is important, and mismatches may lead to erroneous irrigation scheduling, and consequently, reduced crop yields due to under or over-irrigation.

Fig. 4 Field capacity, wilting point and plant available water as a function of texture class. Adapted from Ohio State University (2005) *Ohio Agronomy*. 14th edn. Ohio State University.

Use of TAW and RAW in hydrological models

The goals of most agro-hydrological models are similar, i.e., to predict the soil water balance and crop yield. However, they may differ considerably in the way they describe and parameterize the system. Process-based models solve the water flow with the Richardson-Richards equation coupled with a sink term to account for root water uptake. Although these models represent the state-of-the-art in vadose zone hydrology models, they require detailed soil hydraulic parameterization (water retention and hydraulic conductivity). On the other hand, the “bucket” or compartment models use much simpler water transfer calculations. These models, such as Aquacrop (FAO), implement TAW in their water balance computing routine, treating the soil as a reservoir (bucket analog) with upper (FC) and lower (WP) limits of available water. These water balance “bucket” models are extensively used to describe land surface processes at large scales, especially when coupled with General Circulation Models (GCMs). Applications of TAW to evaluate soil water balance at a regional scale requires resetting its input parameters, moving from localized measurement to mapping, given that the larger the scale the greater the level of uncertainty.

Use of TAW and RAW as ecological indicators

Given the simplified description of the soil water balance provided by TAW and RAW, these indicators are commonly integrated with lumped models to describe the hydrological and ecological functioning at ecosystem scales. Estimating the maximum amount of water a soil can hold, aligned to high-temporal resolution data on soil water content status retrieved from remote sensing, is an important strategy to identify “pools” of potential transpirable water across ecosystems and how they shift over the temporal scale. This information is required to investigate the interactions of soil water and climate, especially the feedback between land surface evapotranspiration and precipitation, with consequent impacts on net primary productivity of terrestrial ecosystems and biogeochemical cycles (e.g., nitrification and CO₂). The main natural factors controlling soil water storage gradients across ecosystems are those related to pedological processes (e.g., parent material, weathering agents and local climate), resulting in soil groups with different thickness and texture, which in part control the vegetation dynamic and its feedback exerted on soil water fluxes.

Concluding remarks

Indicators of plant available water commonly consider upper and lower bounds based on soil hydraulic behavior alone. However, plant water use and development are also affected by other factors, most importantly by mechanical and aeration constraints. Soil water availability and gas diffusion rate (e.g., O₂ and CO₂) within the soil profile are dynamic processes that vary greatly in space and time according to climate variables, plant characteristics, soil hydraulic properties, and soil water status. Single values of water content or water potential alone cannot portray the adequate or critical conditions to which plants are exposed.

All the static limits (FC, WP, LP) are actually dynamic and depend on soil hydraulic properties, root distribution and extent, depth to the water table, as well as soil compaction and aeration status of the soil. Accounting for these factors will improve our prediction of plant water use and irrigation timing, even if just involving empirical adjustments to the simplified linear approaches.

Abstract

Herbaceous plants can lose many times their own weight in water daily. Such transpirational losses may lead to plant water deficit, which constrains leaf expansion and photosynthesis. We review water transport in the soil-plant-atmosphere continuum, considering driving forces and constraints. Measurements that directly or indirectly indicate plant water status are introduced, to underpin their use in crop irrigation scheduling. In planta mechanisms (hydraulic and chemical signaling) regulating plant physiological responses provide opportunities to alter plant genetics or management (including irrigation) to increase plant water use efficiency, improve species selection in managed systems, and better understand vegetation dynamics of natural ecosystems.

Key points

- Describe the driving forces for water movement in the soil-plant-atmosphere continuum.
- Recognize how to measure plant water status using various techniques.
- Appreciate how plant water status measurements can be used in irrigation scheduling.
- Understand how hydraulic and chemical signals regulate plant responses to water deficit.

Introduction

Water constitutes the largest single chemical component of plants, yet daily water losses via plant transpiration can greatly exceed the volume of water within herbaceous plants. When uptake of soil water by plant roots is less than transpiration requirements (determined by the evaporative demand of the atmosphere), plant water deficit ultimately occurs. Various measurements of plant water status are useful for different disciplines, from irrigation scheduling to minimize or regulate crop water deficit to fundamental studies assessing the impact of climate change on natural ecosystems. Decreased plant water status affects numerous plant processes including cell expansion (which is the most sensitive to water deficit), stomatal closure and photosynthesis. Soil drying decreases leaf water potential and alters root-to-shoot chemical signaling, which regulates these processes. An enhanced understanding of these processes provides opportunities for crop management to minimize environmental impacts of agriculture while maintaining food production. Moreover, such knowledge helps refine models forecasting the impact of climate change on natural plant communities, and supports prediction of the success of tree-planting efforts to mitigate the impacts of climate change.

Water in plants

Water normally constitutes more than 90% of fresh weight in herbaceous plants, and more than 50% in woody plants. Most of this water (60–90%) is located within the cells, with the remainder in the cell walls and intercellular spaces. The water in cell walls and intercellular spaces forms a continuum (the apoplast) throughout the plant.

The total volume of water within a plant is very small in relation to the total volume of water transpired during its lifetime. Even on a daily basis, the volume of water within plants is insufficient to account for daily transpiration requirements on a warm, sunny day. Stomatal opening to allow CO₂ absorption for photosynthesis (A) allows water loss as transpiration (E) that can be considered as the 'cost' that plants incur, with their ratio (A/E) defining instantaneous water use efficiency. To maximize photosynthesis and provide carbohydrates for sustaining vegetative and reproductive growth, stomata must remain open for as long as possible during daylight periods, but this also maximizes transpiration.

Water has many functions within plants:

- maintaining cell and tissue turgor to allow cell enlargement (growth) and structural integrity.
- transport of mineral and organic solutes within (xylem and phloem) cells throughout the plant.
- participation in metabolic activities including CO₂ reduction in photosynthesis.
- transpirational cooling to avoid excessive daytime heating from incoming solar radiation.

Plant water status determines its growth and development, crop productivity in agricultural systems, and plant survival in natural systems. Plant water status either directly or indirectly affects almost every plant physiological process, although the sensitivity of various processes varies considerably. It is determined by various atmospheric, plant, and soil factors:

- Soil water availability
- Root capacity to absorb water
- Tissue hydraulic conductance (the ability to transport absorbed water)
- Stomatal responses that regulate transpiration (water loss to the atmosphere)
- Atmospheric evaporative demand (determined by radiation, humidity, temperature, wind)

Plant water status is commonly characterized by its water potential (Ψ), which is a measure of its free energy status that determines the direction of water movement within the soil-plant-atmosphere system. Ψ represents the work involved in moving 1 mole of pure water from a selected point within the plant (or soil) to a reference point at the same temperature and at atmospheric pressure. Ψ varies from zero at the reference point to negative values within the plant and soil. It is normally measured in units of pressure, with megapascals (MPa) being conventional.

Leaf water potential (Ψ_{leaf}) is determined by water loss to the atmosphere by transpiration (E) and water absorption from the soil, which depends on soil water potential (Ψ_{soil}) and the combined resistance to water movement within the roots and shoots (r). Eq. (1) describes these relationships:

$$\Psi_{\text{leaf}} = \Psi_{\text{soil}} - E/r \quad (1)$$

In saturated soils, with all the pore spaces filled with water, Ψ_{soil} approaches 0 MPa (the Ψ of pure water with no stresses). However, solutes (such as salts) in the soil solution decrease its osmotic potential and thus lower Ψ_{soil} . As water drains from the pore space due to gravity, Ψ_{soil} decreases further. In well-drained sandy soils with larger pore spaces, weak matric forces holding water molecules to the soil particles decrease Ψ_{soil} (–0.01 MPa is typical) (see Capillarity). In clay soils with smaller pore spaces, stronger matric forces result in lower Ψ_{soil} after drainage (typically –0.03 MPa). Evaporation from soil surfaces also depletes water, which decreases Ψ_{soil} . However, in vegetated soils, root water absorption to support transpiration has the greatest effect in lowering Ψ_{soil} . Together, evaporation and transpiration comprise evapotranspiration (ET). Along with soil texture and pore structure, ET determines changes in soil water content and hence, the rate of Ψ_{soil} decline in drying soils.

For transpiration to occur, Ψ_{leaf} must be lower (more negative) than Ψ_{soil} . When transpiration ceases (for instance, during night-time), Ψ_{leaf} tends to equilibrate with Ψ_{soil} . In the absence of significant night-time transpiration, leaf water potential by dawn (or after sufficient time to equilibrate with null transpiration) is considered a proxy Ψ_{soil} . Ψ_{leaf} tends to equilibrate with that of the wettest part of the rootzone, such that a few roots in moist deeper soil layers can take up sufficient water to sustain leaf water status.

Increasing evaporative demand (quantified by vapor pressure deficit, VPD) increases transpiration and hence (if Ψ_{soil} remains constant) decreases Ψ_{leaf} . Some plant species close their stomata to limit transpiration at greater VPDs to prevent damaging leaf water deficits. Greater evaporative demands during the night coupled with incomplete stomatal closure prevent Ψ_{leaf} completely equilibrating with Ψ_{soil} and cause some nocturnal transpiration (typically <10% of day-time transpiration). Inter- and intra-specific variation in the ability to limit transpiration at high day-time VPDs and at night have been proposed as plant breeding targets for water-limited environments (Coupel-Ledru et al., 2016).

Since stomata close as Ψ_{leaf} decreases, thereby limiting CO₂ uptake, both soil and atmospheric dryness restrict plant carbon gain. Global warming increases air temperatures and evaporative demand, and consequently ET. As both soil drying and greater ET decrease Ψ_{leaf} and, in turn, stomatal aperture, models predict that global temperature increases should decrease plant carbon fixation (Grossiord et al., 2020).

During daylight periods, water absorption lags behind transpiration due to the high resistance to water flow from soil into root xylem tissue. As atmospheric evaporative demand increases during the morning, transpiration increases, which lowers the water potential of cells from which water is evaporating. Within the plant, water moves from non-evaporating parenchyma cells inside the leaf (with a higher Ψ), toward the evaporating cells (with a lower Ψ), establishing a Ψ gradient. This gradient is transmitted throughout the plant-soil system, enabling continuous water movement. Lower evaporative demand in the late afternoon decreases transpiration. However, water uptake by roots continues until parenchyma cells fully rehydrate. When Ψ_{leaf} equals Ψ_{soil} , which usually occurs during the night, plant and soil water status are in equilibrium, and root water uptake ceases.

Plant water status indicators

Direct indicators of plant water status

Relative water content

Plant water content is the fraction of the total fresh tissue weight that is water, determined on either a fresh- or dry-weight basis. Since this varies considerably between different plant tissues and organs (that vary in tissue density), it is usually normalized according to maximal water content. This relative water content (RWC) is the water content of plant tissue or a plant organ relative to its maximum water content when it is fully hydrated (i.e., saturated). RWC measures the degree of tissue hydration, and is expressed as:

$$\text{RWC} = (\text{FW} - \text{DW}) / (\text{SFW} - \text{DW}) \quad (2)$$

where FW is the fresh weight (grams), DW the dry weight (grams), and SFW is the saturated (or turgid) fresh weight (grams).

Water potential and its components

Plant water status is most commonly measured as water potential (Ψ). Total water potential (Ψ) comprises the osmotic (solute) potential (Ψ_s), pressure potential (Ψ_p), matric potential (Ψ_m), and gravitational potential (Ψ_g) according to:

$$\Psi = \Psi_s + \Psi_p + \Psi_m + \Psi_g \quad (3)$$

Osmotic potential (Ψ_s): results from dissolved solutes in cell sap and is proportional to solute concentration and inversely proportional to cell water volume. In plants, Ψ_s is always negative and decreases as solutes concentrate as the plant dehydrates. Pressure potential (Ψ_p) is a measure of tissue turgor produced by the diffusion of water into the protoplast (mainly the vacuoles) of cells enclosed by largely inelastic cell walls. This produces an outward force against the cell walls that is opposite to the inward movement of water. In living cells, Ψ_p is typically positive (except at plasmolysis when $\Psi_p = 0$). However, in xylem conduits where transpiration maintains tension within the water column, Ψ_p is negative.

Matric potential (Ψ_m): arises from the action, on water, of electrostatic forces of attraction associated with cell wall and colloidal surfaces, and of capillary forces associated with narrow transport conduits. In plants it is considered to be negligible but is the dominant component of soil water potential. For the same volume of soil water, Ψ_m is typically lower in soils with smaller pores (clay soils). Thus, root water extraction from these soils requires even lower plant water potentials.

Gravitational potential (Ψ_g): results from gravitational forces acting on the water within plants and is only significant in very tall trees as its gradient is 0.01 MPa m^{-1} .

In most situations, total plant water potential is considered as the sum of the pressure potential (Ψ_p) and osmotic potential (Ψ_s). As both these components depend on tissue water content, RWC is related to Ψ_s and Ψ_p , and thus Ψ (Fig. 1). In a fully hydrated plant, RWC equals 1, Ψ_p is positive, Ψ_s is negative, and Ψ (the sum of Ψ_p and Ψ_s) equals zero. As RWC progressively declines, both Ψ_p and Ψ_s decline, and consequently Ψ becomes more negative. When RWC has declined sufficiently for Ψ_p to equal zero, the plant loses turgor and wilts.

Measuring plant water potential

Several different methods are available to measure plant water potential. The pressure-chamber method can rapidly measure Ψ of whole leaves or stems in the field. Traditional thermocouple psychrometry and hygrometry can accurately measure small tissue samples (e.g., a leaf disc), but require very stable environmental conditions and are unsuitable for field use. However, stem and leaf psychrometers are able to overcome these problems and are a promising tool for continuous in situ measurements of water potential (Dixon and Tyree, 1984). Pressure potential (Ψ_p) can only be measured directly by the pressure microprobe, which is inserted into cell protoplasm, but this technique is generally restricted to laboratory measurements. However, the development of pressure potential probes coupled to magnetic devices allows continuous measurements of leaf turgor in several species (Zimmermann et al., 2013), with potential uses for irrigation scheduling.

In practice, both Ψ_{leaf} and Ψ_s are routinely measured, with Ψ_p calculated as the difference between Ψ_{leaf} and Ψ_s . Osmotic potential (Ψ_s) is commonly measured by either thermocouple psychrometry or hygrometry after freezing and thawing the sample to break cell membranes and reduce Ψ_p to zero. The pressure chamber can also be used to construct a pressure–volume curve, using the relationships illustrated in Fig. 1 to determine Ψ_s from coupled measurements of Ψ_{leaf} and relative water content during leaf dehydration. These pressure–volume curves also yield other parameters relevant to plant cell water relations such as RWC, Ψ_{leaf} at

Fig. 1 Höfler-Thoday diagram illustrating the relationships between total water potential (Ψ), pressure potential (Ψ_p), osmotic potential (Ψ_s), and relative water content (RWC) as a cell or tissue loses water from a fully turgid state. Full turgor, and wilting are indicated by arrows. Adapted from Jones HG (2014) *Plants and Microclimate*. Cambridge: Cambridge University Press, with permission.

turgor loss point (i.e., when $\Psi_p = 0$), Ψ_s at full turgor, or bulk elasticity modulus (ϵ) or the rate of change of Ψ_p with change in cell volume (V) in turgid cells ($\epsilon = V \cdot \Delta\Psi_p / \Delta V$).

Indirect indicators of plant water status

Soil water status

Soil drying is easily quantified using a range of sensors that determine either volumetric soil water content (e.g., time domain reflectometry (TDR) probes that measure soil dielectric permittivity, and apply an empirical equation to convert it to water content) or soil water potential, Ψ_{soil} (e.g., tensiometers). The relationship between these variables is known as the soil moisture release curve, with soil texture, pore structure and organic matter content determining how much water the soil can hold at a given water potential. Although variation in Ψ_{soil} determines plant physiological responses, it is often more convenient to measure these responses directly, as Ψ_{soil} varies spatially and it can be difficult to know (especially in large trees) where in the soil the plant is extracting water from, and thus where sensors should be placed. This problem is compounded in large orchards, where it is impossible to instrument every tree.

Stomatal conductance

Stomatal conductance (g_s) depends on the number of stomata per unit leaf area (stomatal density) and the degree of stomatal opening. In well-watered plants, larger g_s should increase transpiration thereby decreasing Ψ_{leaf} . Stomatal closure can prevent further decreases in Ψ_{leaf} by reducing transpiration. Nevertheless, decreased Ψ_{leaf} can induce stomatal closure as the soil dries, thereby decreasing g_s . Thus, g_s and Ψ_{leaf} are intimately connected, as discussed more fully in the section Stomatal Responses. Both dynamic and steady-state diffusion porometers, and infra-red gas analyzers (IRGAs) can rapidly measure stomatal conductance, although this variable changes rapidly throughout the day as environmental conditions (e.g., evaporative demand) fluctuate.

Sap flow

Sap-flow sensors can continuously measure transpiration flow in stems, trunks and branches as the ascent of sap within xylem tissue (Vandegehuchte and Steppe, 2013). Sap flow rates are usually directly related to stomatal opening, increasing during the morning to maximum values and then decreasing with stomatal closure in the late afternoon (Fig. 2a). However, they can be out of phase with transpiration when water is stored in stems or branches (capacitance effects). All sap flow sensors measure changes of temperature along the stem after applying heat at a certain point, based on the principle that the applied heat is transported by the sap moving through the sapwood and the velocity of this transport is positively related with sap flow rate.

The various techniques to measure sap flow rate can be grouped in two approaches. The stem (or trunk) sector heat-balance method continuously electrically heats a section of the entire stem circumference and measures axial and radial heat-loss. The mass flow rate of sap is calculated as a function of the heat dissipated by the ascending sap. Alternatively, the heat-pulse method places the heater centrally and temperature sensor probes (either upstream and downstream sides) inside the trunk and calculates sap velocity as a function of the time required by the flowing sap to transport heat to a particular location.

Sap flow can be measured as sap flow rate (i.e., the rate of water mass change per unit time, usually g h^{-1}) or sap flux density (the rate of water volume per unit sapwood volume and time). While sap flow measurements are all based on the heat-balance

Fig. 2 Changes in environmental conditions and physiological responses of a silver birch (*Betula pendula*) tree. Panels (a) and (b) focus on sap flow and radial stem growth on Day 1. As sap flow increases during the day, the trunk supplements water from the root system with internal water reserves, principally from the phloem parenchyma; causing the stem to shrink. Stem growth occurs during the night when sap flow decreases. Atmospheric evaporative demand or vapor pressure deficit (VPD - c) is the driving force for sap flow (d). Diurnal fluctuations in stem diameter that were prominent on Days 1 and 2 (e) diminish after rain events rehydrate the soil on Days 5 and 6 (f). Deploying sensors that measure these variables can aid irrigation scheduling, particularly if the data can be visualized in real-time via a digital dashboard. Shaded rectangles indicate period between sunset and sunrise. A.D. Hirons, unpublished.

approach, techniques that measure sap flux density are diverse and can use either of the two approaches. Most of these techniques cannot distinguish between low and zero flows and cannot detect negative (i.e., descending) flows, but the most advanced techniques based on the heat-pulse method, such as the heat ratio technique, can detect very small or even reverse flows.

Stem diameter variations

Stem or trunk diameter fluctuates diurnally in transpiring plants, according to their water status (De Swaef et al., 2015). Stem diameter decreases during the morning (Fig. 2b), as rapid transpiration rates are partly supported by some water from stem (mostly phloem) tissue being incorporated into the transpiration stream. Rehydration of this tissue during the afternoon (as transpiration slows with decreased evaporative demand) increases stem diameter. Rehydration continues overnight with continued water uptake from the soil. Commonly, stem diameter has a maximum daily value just before dawn (coinciding with the maximum daily plant water potential), and a minimum daily value in the early afternoon (as plant reaches its minimum daily water potential). The magnitude of the daily stem contraction depends on atmospheric evaporative demand and plant water status, and increases with increasing plant water deficit. Consequently, these variations in stem diameter can very sensitively measure plant water status.

Stem growth is indicated by increased daily maximum stem-diameter values. Decreased growth rates, due to soil drying or other environmental stresses, are apparent as a change in the slope of daily maximum stem-diameter values. In mature plants, daily maximum stem-diameter values tend to be more constant. Since plant age and developmental stage affect the sensitivity of stem diameter fluctuations to evaporative demand, monitoring plant water status in this way usually requires reference baseline monitoring of well-watered controls grown in the same conditions. Sensors incorporating sensitive pressure transducers, known as linearly variable differential transducers (LVDT), connected to data loggers allow stem diameter to be continuously monitored.

Leaf or canopy temperature and spectral reflectance techniques

Transpiration cools the leaf, thus canopy temperature (i.e., average temperature of total leaf surface) is often appreciably less than the air temperature. Partial stomatal closure, in response to increasing evaporative demand or soil drying, increases canopy temperature as less heat is dissipated through the evaporation of water. Since absolute canopy temperature depends on prevailing air temperatures, it is conventional to calculate a Crop Water Stress Index (CWSI):

$$\text{CWSI} = ((T_{\text{canopy}} - T_{\text{air}}) - (T_{\text{wet}} - T_{\text{air}})) / ((T_{\text{dry}} - T_{\text{air}}) - (T_{\text{wet}} - T_{\text{air}})) \quad (4)$$

where T_{air} is air temperature, T_{canopy} is canopy temperature, T_{dry} is the temperature of a dry reference surface and T_{wet} is the temperature of a wet reference surface. Thus, the decrease in canopy temperature caused by transpirational cooling is expressed as a function of the maximum cooling possible in that environment. Typical reference surfaces are leaves sprayed with water (wet reference) or covered in vaseline to prevent transpiration (dry reference), or surrogate leaves such as pieces of card (Fig. 3). Canopy

Fig. 3 False color thermal image superimposed to visual image of a soybean (*Glycine max*) canopy comprising individual well-watered plants (light blue-grey colors) and droughted plants (orange-brown colors) grown in pots in a greenhouse, with the bench indicated by dark-blue colors. Surface temperature is provided by the scale at right. The dry reference surface is the arrowed yellow rectangle, while individual well-watered plants and droughted plants are identified by placing red masking tape on the leaves in the letters H and D respectively (also arrowed). J. Puértolas, unpublished.

temperature is most commonly measured with infrared thermometers or thermal infrared cameras, with thermal images easily able to discriminate well-watered or droughted plants.

Reflectance indices are based on statistical techniques to determine the most physiologically relevant wavelengths that are correlated with plant and soil water content (Gerhards et al., 2019), including the

- Green-to-red ratio index (GRI) based on the vegetation reflectance (R) ratio at 550 nm and 670 nm (R_{550}/R_{670}).
- Water band index (WBI) based on the vegetation reflectance (R) ratio at 900 and 970 nm (R_{900}/R_{970}).
- Normalized Difference Vegetation Index (NDVI) based on vegetation reflectance (R) in the near infrared (NIR) and visible red (VR) regions thus:
 (1) $NDVI = (R_{NIR} - R_{VR}) / (R_{NIR} + R_{VR})$
- Water balance index (WABI) based on independent changes in leaf water content (1500 nm) and nonphotochemical quenching photoprotection (531 nm).

Whereas GRI relies on cheaper (multispectral or visible light) sensors, the others require more expensive hyperspectral sensing. As reflectance in specific wavelengths is determined by plant metabolite concentrations (e.g., photosynthetic pigments), ratiometric techniques are needed to discriminate water deficit responses from those influenced by other stresses (e.g., nutrient stress, pest or disease attack). As with all indirect indicators of plant water status, the sensitivity of these indices to water deficit will vary between species and thus determine their utility in irrigation scheduling in managed systems or vegetation monitoring in natural systems.

Applying plant-water relations in irrigation scheduling

These indicators of plant water status may be applied to assist growers in irrigation scheduling or to explore physiological stresses of plants in natural systems. Plant-based measurements offer an advantage over soil-moisture monitoring or estimating crop evapotranspiration (ET) requirements in that the actual unit of production (the plant) is being assessed. Nevertheless, soil or micrometeorology-based calculations determine the irrigation volume to apply, whereas plant water status indicators can indicate when to irrigate, but not the amount. Thus plant-based measurements can supplement other sources of data to inform grower decision-making.

Interpreting plant water status indicators requires comparison with previous data usually attained with fully irrigated plants. Such comparisons establish threshold values (e.g., a maximum allowable daily stem-diameter contraction; a minimum stomatal conductance), with irrigation needed when these values are exceeded. To distinguish variation in plant water status due to insufficient soil water from variation due to atmospheric demand, plant water status data are often normalized according to evaporative demand.

Irrigation timing can be determined by predawn or midday measurements of leaf water potential, based on prior relationships between Ψ_{leaf} and growth in the species of interest (Améglio et al., 1999). The aim is to keep Ψ_{leaf} above threshold values, at which growth is limited, by irrigation. Since Ψ_{leaf} can rapidly vary due to fluctuations in evaporative demand, stem water potential (Ψ_{stem}) is sometimes measured by enclosing leaves (to prevent transpiration) an hour before the measurement. While Ψ_{leaf} and Ψ_{stem} are sensitive measures of plant water status (in species that do not maintain Ψ_{leaf} as the soil dries), they are destructive, time-consuming

and require a skilled operator. These discrete manual measurements can attain only a limited amount of data in comparison to measurements that are readily automated.

Recent developments in sensor and data technology allow plant water status to be continuously monitored, using displacement transducers that measure stem diameter variations (LVDT) and sap-flow sensors (Steppe et al., 2008). Using LVDT sensors, irrigation scheduling can occur automatically when the selected indicator of plant water status reaches a defined limit. Trunk-diameter measurements with LVDT sensors are closely correlated with variations in plant water status in many tree species. Daily stem shrinkage, the difference between daily maximum values and daily minimum values (Fig. 2b), can detect water stress with irrigation protocols involving: (1) selecting the stem shrinkage most suitable for an individual species and particular growth stage, and (2) relating stem shrinkage to reference values of well-watered crops and normalizing them for VPD (3) to determine empirically the relationships between stem shrinkage and irrigation volume required. Placing several LVDT sensors within a crop can account for plant-to-plant variability to ensure average crop response is measured.

Since LVDT sensors do not directly determine the irrigation volume required, sap-flow sensors can be used to determine the amount of water consumed by the plant. Irrigation scheduling can then replenish this water at specified times or time intervals. Nevertheless, the cost of these sensors means that relatively few can be deployed within a crop, thus variability between plants needs to be considered when scaling from single plants to crops. Since identifying individual plants that represent the “average response” of the crop is essential for determining sensor placement, and thus adequate management of sensor-based irrigation, there is increased interest in remote sensing of the entire cropping area to assist irrigation scheduling decisions.

Remote sensing of plants offers advantages that (1) the measurement itself does not perturb plant physiology (e.g., leaves are removed to determine Ψ_{leaf} , inserting sap flow sensors into tree trunks can induce wound responses) and (2) the entire canopy evapotranspiration can be assessed. Multiple platforms (e.g., drones, aircraft, satellites) can image crop canopies, with biomass determinations, evapotranspiration estimates and spectral reflectance indices (indicating crop performance) all providing useful information to the irrigator.

Possibly the most useful technique involves thermal imaging of the crop to calculate a Crop Water Stress Index. Thermal imaging is especially useful across a large cropping area, to identify individual plants (or groups of plants) that may be water-stressed due to local variation in soil properties (e.g., limited soil volume) or failures in irrigation hardware (e.g., blocked drippers). Any irrigation scheduling decisions based on remote sensing require efficient image processing to minimize time between image capture, data processing and providing recommendations to the grower (Khanal et al., 2017).

Physiological responses to plant water deficits

Plant water deficit occurs when plant water status is reduced sufficiently to affect normal plant functioning (e.g., plant growth, stomatal conductance, photosynthetic rate). Absolute values of these variables are poor indicators of water stress, as they are affected by complex interactions of atmospheric, plant (phenological stage and water deficit history) and soil factors, that can modify plant response at a given water potential. Commonly, these values are expressed in relation to those of similar well-irrigated plants.

Plant water deficits are caused by limited root water absorption (e.g., because of dry, salty, cool, or poorly aerated soil) or high atmospheric evaporative demand. Plant water deficits induced solely due to large evaporative demand occur because water potential in transpiring leaves declines as leaf tissues lose water. These deficits depend on atmospheric conditions and are typically greatest at midday and on hot, dry, windy, sunny days. Plant water deficits induced by decreased soil water potential become progressively more intense, until alleviated by rain or irrigation. Since dry atmospheres increase evapotranspiration and therefore the rate of soil drying, they accelerate soil water deficits.

Temporal changes in Ψ_{stem} and sap flow as the soil dries are indicated (Fig. 4). Prolonged soil drying decreases Ψ_{stem} over time until the plant is unable to absorb sufficient water to rehydrate at night. Further declines in Ψ_{stem} promote stomatal closure and sap flow is reduced to conserve water. When plants are unable to recover cell and tissue turgor, which occurs at a threshold soil-water potential value (approximately -1.5 MPa in many herbaceous species, but typically lower, between -2 MPa and -3 MPa, in woody species), the plant permanently wilts.

Severe water deficits can even occur in plants growing in moist soil or hydroponic nutrient solutions, when high evaporative demand causes large transpiration rates that exceed the rate of water uptake by roots. These situations inhibit day-time growth, but can be compensated by night-time growth if night temperatures are not limiting. Since recurrent atmospheric water deficits can reduce yield in intensive greenhouse crop-production systems, fogging systems can be used to prevent them.

Different plant processes show variable sensitivity to water deficits (Table 1). Processes such as cell enlargement, cell wall synthesis, and protein synthesis are very sensitive, being affected by relatively small reductions in Ψ (Hsiao, 1973). Other processes, such as stomatal opening and CO_2 assimilation, generally require larger reductions in Ψ . As plant water deficits intensify, an increasing number of plant processes are affected (Table 1), and there can be complex interactions between them. Two of these processes, expansive growth and stomatal responses, are discussed more fully below.

Fig. 4 Changes in environmental conditions and physiological responses of a holm oak (*Quercus ilex*) experiencing a drying cycle within a controlled environment room. Diurnal fluctuations in vapor pressure deficit (VPD—kPa) (a) remain stable during this period. As soil moisture (g g^{-1}) (b) declines, stem water potential (MPa) (c) does not return to well-watered values of approximately 0 MPa overnight. Further declines in water potential (c) promote stomatal closure and the decline in sap flow (d). Shaded rectangles represent the night period. A.D. Hirons, unpublished.

Table 1 Plant process affected by water stress and their sensitivity.

Process affected	Sensitivity to stress			Remarks
	Very sensitive			
	Relatively insensitive			
	Reduction in tissue Ψ required to affect process ^a			
	0 MPa	1 MPa	2 MPa	
Cell enlargement				Fast-growing tissue
Wall synthesis				
Protein synthesis				Fast-growing tissue
ABA accumulation				Depends on species
Stomatal opening				
CO ₂ assimilation				Depends on species
Respiration				
Sugar accumulation				

Length of the horizontal lines represent the range of stress levels within which a process becomes first affected. Dashed lines signify deductions based on more tenuous data.
^aWith Ψ of well-watered plants under mild evaporative demand as the reference point.
Hsiao TC (1973) Plant responses to water stress. *Annual Review of Plant Physiology* **24**: 519–570.

Expansive growth

Since cell enlargement is largely driven by turgor pressure exerted on cell walls, it is especially sensitive to water deficit, which is very important as it reduces leaf area expansion (the photosynthetic surface). Cellular turgor pressure (Ψ_p) is directly related to cell expansion according to the Lockhart equation:

$$dV/dt = m/\Psi_p - \Psi_{th} \tag{5}$$

where the relative change in cell volume (V), with time (t), depends on Ψ_p above a threshold value (Ψ_{th}) below which no cell expansion occurs and cell wall extensibility (m). Increases in cell wall extension during growth are irreversible. Typically, Ψ_{th} is normally only slightly less than Ψ_p values, thus small reductions in Ψ_p can inhibit growth. Both m and Ψ_{th} can vary with previous exposure to water stress and growing conditions. To maintain growth at lower Ψ_p in dry soil stress, plants can adapt by either reducing Ψ_{th} and/or increasing m . Although Eq. (5) provides an elegant conceptual theory, and is now used in functional-structural plant growth models (Coussement et al., 2018), most recent work emphasizes that cell wall biochemistry regulates expansive growth. While diurnal fluctuations in leaf turgor (e.g., caused by fluctuating evaporative demand over the course of a day) seem important in determining leaf elongation rate over minutes to hours, over days turgor seems less important with plant hormones regulating cell wall properties (Munns et al., 2000).

Stomatal responses

In well-watered plants growing at relatively low evaporative demands, light conditions and the low CO₂ partial pressure of substomatal cavities primarily determine stomatal opening. Under these conditions, the stomata are fully open during daylight periods, maximizing photosynthetic rates.

With soil or air drying, as leaf water potential declines, stomatal guard cells lose turgor and their aperture decreases to reduce plant water losses, thus compromising photosynthesis as access to CO₂ is reduced. Nevertheless, stomatal closure can occur even when leaves are fully turgid (Gollan et al., 1986), especially in some (isohydric) species in which partial stomatal closure acts to maintain Ψ_{leaf} homeostasis. In anisohydric species, stomata are less sensitive to Ψ_{leaf} which typically declines. While these stomatal responses are relatively rapid, stomata respond relatively slowly in plants that are recovering from water stress. Although re-watering can rapidly (within minutes) increase Ψ_{leaf} to well-watered values, stomatal conductance can take several hours, or even days, to recover.

In angiosperms, where guard cells are smaller than surrounding epidermal cells, guard cell turgor is usually decoupled from the turgor of surrounding epidermal cells to avoid the mechanical advantage of the large epidermal cells over the smaller guard cells. Regulated solute movement (especially K⁺ ions) to and from the guard cells changes their osmotic potential, increasing or decreasing their turgor compared with epidermal cells at the same water potential. Plant water deficits promote the efflux of K⁺ ions from guard cells, causing loss of cell turgor, which induces stomatal closure (Buckley, 2019). Re-watering induces synchronized changes in K⁺ concentration and guard cell water content prior to stomatal opening. These fluxes of ions require ion transport activation that are mainly regulated by the phytohormone abscisic acid, which is ubiquitously synthesized by plant cells in response to water stress.

Root signals and their application in agriculture

Traditional theory holds that a reduction in soil water potential decreases plant pressure potential, thereby decreasing cell expansion and promoting stomatal closure, a paradigm termed “hydraulic signaling” (Christmann et al., 2013). However, leaf growth inhibition and partial stomatal closure can occur even without changes in pressure potential of leaf cells, with these processes related more strongly to changes in soil water status than to leaf water status. Alternatively, the “chemical signaling” paradigm holds that plants can ‘sense’ drying soil in the root zone and communicate this information to the leaves by a means other than reduced leaf water status. Much work on chemical signaling has focused on the potent anti-transpirant hormone abscisic acid, ABA (Wilkinson and Davies, 2002). Considerable debate has concerned whether hydraulic or chemical signaling dominates *in planta*. These signaling systems are not mutually exclusive, as low plant water status stimulates ABA biosynthesis and enhances stomatal sensitivity to ABA, while increased ABA levels decrease stomatal conductance (thereby maintaining Ψ_{leaf}) and leaf hydraulic conductance while increasing root hydraulic conductance.

While there is broad consensus that ABA is important in regulating stomatal behavior through the mechanisms mentioned in the previous section (since ABA-deficient mutants have high stomatal conductance and low Ψ_{leaf}), two theories have emerged regarding its action *in planta*. “Root-to-shoot ABA signaling” holds that ABA is produced in roots (especially the root tips) in drying soil and is transported to leaves in the xylem sap, where it induces stomatal closure before Ψ_{leaf} decreases. Alternatively, “shoot-to-root ABA signaling” holds that the rate of shoot ABA biosynthesis increases in response to decreased Ψ_{leaf} , or that ABA is redistributed in the leaves toward the guard cells, and that much of this ABA also moves to the roots to increase root ABA accumulation. Given the importance of ABA in preventing plant desiccation, it seems plausible that both signaling systems operate (Li et al., 2018), with their relative magnitude determined by whether the roots or shoots are the first to perceive soil drying or increased evaporative demand respectively.

ABA can induce stomatal closure in isolated epidermis at nanomolar concentrations (typically found in the xylem sap of well-watered plants). Quantitative variation in ABA responses between different plant species might be explained by variation in the ABA concentrations required to induce stomatal closure. For example, while the ABA concentrations in maize xylem sap are sufficient to cause stomatal closure, those in wheat are not. The distribution of xylem-supplied ABA within the leaf seems critical in determining whether the stomata close. In well-watered plants, xylem sap of many species is relatively acidic, causing much of the ABA to be partitioned into mesophyll cells away from the guard cells. As the soil dries, the xylem sap becomes more alkaline, which results in more of the ABA reaching the guard cells. However, soil drying does not alter xylem sap pH in some species yet the stomata close (Sharp and Davies, 2009), suggesting the existence of other chemical root signals.

Other plant hormones such as jasmonates and strigolactones have demonstrable anti-transpirant action (Huntenburg et al., 2022), whereas others such as auxins and cytokinins can antagonize ABA-induced stomatal closure. Soil drying can alter the concentrations of all of these hormones, which are also involved in regulating other processes such as responses to biotic stress (jasmonates), shoot branching or tillering (strigolactones), cell expansion (auxin) and cell division (cytokinins). Thus, soil drying causes multiple changes in shoot phenotype, with the importance of root-to-shoot and shoot-to-root signaling varying between these different hormones.

Another hormone that seems important in regulating plant responses to soil drying and other stresses such as mechanical impedance is the volatile hormone ethylene (Pandey et al., 2021). In compact soil, ethylene accumulates around the root system thereby inhibiting root growth, which may compromise water uptake. Soil drying increases root concentrations of the ethylene precursor 1-amino-cyclopropane carboxylic acid (ACC), and some of this ACC can be transported to the shoot to enhance ethylene synthesis. However, soil drying decreases shoot ethylene production of many species, which may help the stomata to close since ACC (and ethylene) antagonize ABA-induced stomatal closure. Ethylene also promotes leaf senescence which decreases the

duration of leaf photosynthesis. Thus, genotypes that are less able to produce ethylene may produce higher yields when grown in drying soil.

Recognition of bi-directional hormonal signaling may stimulate commercial application of specific agronomic techniques to enhance crop drought resilience. Although the surgical technique of grafting has long been used in horticultural crops to ensure genetically distinct rootstocks and scions with desirable traits (e.g., disease resistant rootstocks, high quality fruit), modern genome editing procedures can increase or decrease plant hormone signaling. Since plant hormones can have antagonistic effects on root and shoot function (e.g., cytokinins restrict root elongation, but enhance shoot growth), grafting could allow different hormone production in roots and shoots. Attenuating root cytokinin production should increase root elongation in drying soils, while augmenting shoot cytokinin production should sustain vegetative growth as the soil dries. Grafting can increase water use efficiency of commercial crops (Cantero-Navarro et al., 2016), linked to changes in root-to-shoot chemical signaling. Increased understanding of the importance of root-shoot communication may provide opportunities to reconcile crop stress resilience and productivity.

Alternatively, recognition of root-to-shoot signaling has stimulated the development of an irrigation technique that deliberately withholds water from part of the rootzone, by watering alternate furrows or just using one irrigation line of two placed either side of the crop row. Such partial rootzone drying (Dodd et al., 2015) aims to create distinct dry and wet parts of the rootzone, with the former stimulating the production of root signals that restrict vegetative growth and stomatal opening (thereby decreasing water loss) and the latter supplying sufficient water to the shoots to maintain turgor. Such root signaling is dynamic, and is promoted by moderate soil drying when the roots in dry soil still contribute to the transpiration stream, but attenuated by prolonged drying when limited sap flow from the roots in dry soil restricts transmission of the signal. Carefully managing the irrigation volumes to the wet and dry rootzones theoretically provides opportunities to enhance stomatal closure to increase crop water use efficiency, or minimize stomatal closure to maintain photosynthesis. Measuring some of the plant water status indicators described above may allow such precision in irrigation management.

Future opportunities

While agriculture has traditionally emphasized maximizing water use (keeping the stomata open to maintain photosynthesis), this strategy is viable only when sufficient water is available in the soil profile, or supplemental irrigation is possible. Since climate change exacerbates existing tensions between agricultural and domestic, ecological and industrial water use, farmers of the future will need to manage limited water supplies. Adopting deficit irrigation techniques such as partial root zone drying (that supply less water than crop evapotranspiration requirements) provide opportunities to maximize biomass allocation to the harvested portion to increase crop quality. Partially decoupling economic productivity from irrigation water requirements offers opportunities to reconcile some of the competing demands for water.

Understanding plant-water relations is not only useful to develop techniques that improve water use efficiency in agriculture. Climate change impacts on natural plant ecosystems and managed forest systems are mostly linked to higher evaporative demand that decreases soil water availability. Predicting their future capacity to fix carbon in new climatic scenarios and making decisions on adaptive forest management and plant species conservation will depend on understanding relationships between water use and carbon fixation. While knowledge of plant water relations has significantly advanced at the individual plant level, approaches applying the remote sensing techniques described in this chapter (Jones, 2018) will be necessary to respond to this new challenge. As ecosystem complexity increases (e.g., from traditional monoculture cropping to regularly spaced agroecological systems to natural plant systems with vegetation of varying height and structure), understanding how species interactions determine plant water relations will become increasingly important.

Abstract

Water Use Efficiency (WUE) expresses the trade-off between carbon assimilation (or subsequent carbon storage) and water release, two concurrent gas fluxes essential for plant functioning. Here, we review metrics that have been introduced to quantify WUE across spatial and temporal scales and corresponding observational methods. The physiological and environmental dependencies of WUE for crops and unmanaged ecosystems are discussed with a quantitative examination of observed and simulated WUE values. A constrained range of WUE across ecosystems and climates is highlighted. However, WUE increased considerably in the past century in response to growing atmospheric CO₂ concentration and it will likely continue along the same trajectory in the near future.

Glossary

WUE Generic water use efficiency [various units].
WUE_l Leaf scale water use efficiency [$\mu\text{mol CO}_2 \text{ mmol}^{-1} \text{ H}_2\text{O}$] or [$\text{gC kg}^{-1} \text{ H}_2\text{O}$].
iWUE Leaf scale intrinsic water use efficiency [$\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ H}_2\text{O}$].
iWUE^{eco} Ecosystem scale intrinsic water use efficiency [various units].
IWUE Inherent water use efficiency [$\text{gC kPa m}^{-2} \text{ mm}^{-1}$].
WUE^{eco} Ecosystem scale water use efficiency computed with ET [$\text{gC m}^{-2} \text{ mm}^{-1}$].
WUE_T^{eco} Ecosystem scale water use efficiency computed with transpiration [$\text{gC m}^{-2} \text{ mm}^{-1}$].
A_n Net carbon assimilation [$\mu\text{mol CO}_2 \text{ m}^{-2} \text{ leaf s}^{-1}$].
g_s Stomatal conductance [$\mu\text{mol CO}_2 \text{ m}^{-2} \text{ leaf s}^{-1}$].
T Transpiration [$\text{mmol H}_2\text{O m}^{-2} \text{ leaf s}^{-1}$] or [mm h^{-1}] or [mm day^{-1}] or [mm yr^{-1}].
ET Evapotranspiration [mm day^{-1}] or [mm yr^{-1}].
GPP Gross primary production [$\text{gC m}^{-2} \text{ yr}^{-1}$].
NPP Net primary production [$\text{gC m}^{-2} \text{ yr}^{-1}$].
VPD Vapor pressure deficit [Pa].
C_a Atmospheric CO₂ concentrations [ppm] or [Pa].
C_i Leaf internal (or intercellular) CO₂ concentrations [ppm] or [Pa].
WP_{B/Tr} Water productivity as the ratio of biomass to transpiration [$\text{gDM m}^{-2} \text{ mm}^{-1}$] or [kgDM m^{-3}].
WP_{B/ET} Water productivity as the ratio of biomass to evapotranspiration [$\text{gDM m}^{-2} \text{ mm}^{-1}$].
WP_{Y/Tr} Water productivity as the ratio of yield to transpiration [$\text{gDM m}^{-2} \text{ mm}^{-1}$].
WP_{Y/ET} Water productivity as the ratio of yield to evapotranspiration [$\text{gDM m}^{-2} \text{ mm}^{-1}$].
WP* Water productivity normalized per potential ET and CO₂ concentration [$\text{gDM m}^{-2} \text{ day}^{-1}$].
B Produced crop biomass [$\text{gDM m}^{-2} \text{ day}^{-1}$].
HI Harvest Index [–].
Y Agricultural yield [$\text{gDM m}^{-2} \text{ day}^{-1}$].
Rubisco Ribulose-1,5-bisphosphate carboxylase-oxygenase, the key enzyme involved in the first major step of carbon fixation in photosynthesis.

Key points

- Definitions of Water Use Efficiency (WUE) are reviewed and WUE values across scales and ecosystems are provided.
- Water productivity for a given crop is relatively constant for a given CO₂ concentration and potential evapotranspiration.
- WUE dependence on biome type and precipitation is weak.
- Current remote sensing vegetation products are unlikely to properly characterize WUE.
- WUE has been increasing in response to growing atmospheric CO₂ concentration.

Introduction and definitions

Various definitions of Water Use Efficiency (WUE) have been proposed depending on the spatial scale of interest (leaf, plant, or ecosystem level) and productivity aspects of crops and natural vegetation. In its most general form, WUE represents the ratio between the carbon assimilated by, or stored in, vegetation (e.g., Gross and Net Primary Production (GPP, NPP), biomass, yield) and the flux of water released to the atmosphere (e.g., transpiration, evapotranspiration) over the same unit of space and time.

At the leaf scale, the water use efficiency (WUE_l) [$\mu\text{mol CO}_2 \text{ mmol}^{-1} \text{ H}_2\text{O}$] is expressed as the ratio between the instantaneous net carbon assimilation A_n [$\mu\text{mol CO}_2 \text{ m}^{-2} \text{ leaf s}^{-1}$] and transpiration T [$\text{mmol H}_2\text{O m}^{-2} \text{ leaf s}^{-1}$] (Nobel, 2009, p. 404):

$$WUE_l = \frac{A_n}{T}. \quad (1)$$

As WUE_l is known to depend on atmospheric conditions and directly on atmospheric Vapor Pressure Deficit (VPD), a metric that discounts for the role of VPD is the leaf-scale intrinsic water use efficiency (iWUE) [$\mu\text{mol CO}_2 \mu\text{mol}^{-1} \text{ H}_2\text{O}$] or [$\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ H}_2\text{O}$] (Medlyn et al., 2017):

$$iWUE = \frac{A_n}{T} VPD^* = \frac{A_n}{1.6g_s} \quad (2)$$

where VPD* [-] is the VPD computed between the leaf interior and the air at the leaf surface and normalized by atmospheric pressure, g_s [$\mu\text{mol CO}_2 \text{ m}^{-2} \text{ leaf s}^{-1}$] is the stomatal conductance for CO₂, and 1.6 is the ratio between water vapor and CO₂ diffusivity in air.

Considering Fick's law of diffusion, the net assimilation can be expressed as the product of stomatal conductance and the gradient of CO₂ concentration, $A_n = g_s(C_a - C_i)$, and iWUE can be re-written as:

$$iWUE = \frac{g_s(C_a - C_i)}{1.6g_s} = \frac{C_a}{1.6} \left(1 - \frac{C_i}{C_a} \right) \quad (3)$$

where C_a and C_i [-] are the CO₂ concentrations at the leaf surface (often approximated with the atmospheric CO₂ concentration) and the leaf CO₂ internal concentration in the sub-stomatal cavity, respectively. Eq. (3) has three major implications. First, iWUE is solely dependent on C_a and C_i/C_a . Therefore, all plant physiological and environmental controls (except C_a) are summarized in the C_i/C_a value. Note also that a factor of three on the range of C_i/C_a between 0.3 and 0.9 would lead to a factor of seven in iWUE change ($42\text{--}294 \mu\text{mol CO}_2 \text{ mol H}_2\text{O}^{-1}$) at current C_a levels of 420 ppm (Fig. 1), which represents a reasonable expectation for iWUE variability. Second, for constant C_i/C_a , the iWUE scales linearly with C_a , which explains why iWUE has been extensively used in studies looking at CO₂ effects on WUE (e.g., Frank et al., 2015). Third, at least in some classic literature, there has been a consensus that C_i/C_a is a relatively conserved quantity, with values around 0.7 for C₃ plants and 0.4–0.5 for C₄ plants (e.g., Morison and

Fig. 1 Values of iWUE as a function of the ratio, C_i/C_a , between leaf internal (sub-stomatal cavity) and atmospheric CO₂ concentration for three different C_a values (280, 420, and 550 ppm).

Gifford, 1983; Long et al., 2004; Wong et al., 1985). If C_i/C_a is indeed constant, this would automatically imply that leaf-scale iWUE is solely a function of C_a for C_3 and C_4 plants (e.g., $iWUE = 0.1875 \cdot C_a$ for C_3), regardless of differences in plant physiological attributes or environmental conditions. In other words, for a given level of C_a , only two values of iWUE would exist (one for C_3 and one for C_4 plants). The constancy of C_i/C_a across different conditions has been used to explain the conservative behavior of the water used by crops to produce biomass (Steduto et al., 2007). However, C_i/C_a is not as constant across species and environmental conditions as often reported. The C_i/C_a ratio was shown to be affected by VPD (Morison and Gifford, 1983) and recently compiled datasets challenge the idea of a very conservative C_i/C_a value (Lin et al., 2015; Adams et al., 2020). Note also that a decrease of C_i/C_a from 0.8 to 0.7 (i.e., a -12% change) leads to a change in iWUE of +50%. Therefore, minor differences in C_i/C_a can have very important implications for WUE.

As the analysis moves from leaf scale to canopy and ecosystem scale, there are other processes that can influence WUE. First, a plant must compete for water with physical processes such as soil evaporation and drainage. Furthermore, canopy architecture, phenological cycle of vegetation, and, especially, the temporal dynamics of Leaf Area Index (LAI) can have an important role on water use efficiency, independently of leaf-scale physiology. Additional environmental factors such as nutrient availability and water stress can also affect the plant or ecosystem capacity of using water. In analogy with the leaf scale, the ecosystem scale intrinsic water use efficiency ($iWUE^{eco}$) is defined as (Beer et al., 2009):

$$iWUE^{eco} = \frac{GPP}{G_{s,can}} \quad (4)$$

where GPP [$gC\ m^{-2}\ h^{-1}$] is the Gross Primary Production and $G_{s,can}$ [$mol\ m^{-2}\ s^{-1}$] is the ecosystem scale canopy conductance (Lavergne et al., 2019). However, a more widely used and easier to measure metric at the ecosystem scale is the so-called inherent water use efficiency iWUE [$gC\ kPa\ m^{-2}\ mm^{-1}$]:

$$IWUE = \frac{GPP}{ET} VPD \quad (5)$$

where VPD [kPa] is computed using air temperature, and ET [$kg\ H_2O\ m^{-2}\ h^{-1}$] (or equivalently [$mm\ h^{-1}$]) is the ecosystem scale evapotranspiration, which sums the biotic transpiration and the abiotic evaporation from ground and from vegetation interception. More recently, it has been suggested that to better incorporate the nonlinear effect of VPD on ecosystem water use, an underlying water use efficiency, expressed as $uWUE = GPP \cdot VPD^{0.5}/ET$, should be used (Zhou et al., 2014). Alternatively, the basic ecosystem scale water use efficiency, WUE^{eco} [$gC\ m^{-2}\ mm^{-1}$], can be computed as:

$$WUE^{eco} = \frac{GPP}{ET} \quad (6)$$

Eq. (6) is simply the ratio of the gross amount of assimilated carbon and the total evapotranspiration at the ecosystem scale over a given period. A more plant-centered metric is: $WUE_T^{eco} = GPP/T$, where total ET is substituted with only the amount of transpired water T , which depends on plant behavior and its response to environmental conditions. However, WUE_T^{eco} is extremely difficult to measure and WUE^{eco} is generally reported in most studies. The ecosystem scale metrics $IWUE$ and WUE^{eco} are typically computed at the monthly or annual scale since GPP and ET have considerable variability at hourly and daily time scales.

Additional definitions of water use efficiency have been used in agronomy where the focus is on the amount of water used for generating crop biomass, crop yield, or marketable products such as fruits and oil, rather than GPP itself. For these agronomic applications, water use efficiency (often referred to as water productivity) can be measured as: $WP_{B/ET}$ [kg dry or fresh biomass $m^{-2}\ mm^{-1}$ transpiration], $WP_{B/ET}$ [kg dry or fresh biomass $m^{-2}\ mm^{-1}$ evapotranspiration], $WP_{Y/Tr}$ [kg dry matter yield $m^{-2}\ mm^{-1}$ transpiration], or $WP_{Y/ET}$ [kg dry matter yield $m^{-2}\ mm^{-1}$ evapotranspiration] (Steduto et al., 2007, 2012). Often these quantities are expressed in $m^{-3}\ H_2O$ rather than m^{-2} ground $mm^{-1}\ H_2O$. These values are reported for comparing water productivity levels across crops (Table 1) or for a given crop in different climates or agricultural management settings (Zwart and Bastiaanssen, 2004; Katerji et al., 2008; Vico and Porporato, 2015). For non-grain crops, such as sugarcane, cotton, or vegetable oils the water use efficiency is often expressed as the mass of the marketable products divided by the water use, e.g., as kg of sucrose, kg of lint, or kg of oil per $m^2\ mm$ or m^3 of evapotranspiration, respectively.

Table 1 Water productivity $WP_{Y/ET}$ computed as the ratio of yield (total yield—not grain yield) to evapotranspiration [$kgDM\ m^{-3}$] (or equivalently [$gDM\ m^{-2}\ mm^{-1}$]) for major crops.

Crop	$WP_{Y/ET}$ [$gDM\ m^{-2}\ mm^{-1}$]
Wheat	1.1 (0.6–1.5)
Rice	1.1 (0.4–1.6)
Maize	1.4 (0.8–2.4)
Soybean	0.47 (0.3–0.65)
Sorghum	1.2 (0.7–1.7)
Cotton Lint	0.23 (0.14–0.34)

Reported central values and range of variability (in brackets) are synthesized from four review articles (Zwart and Bastiaanssen, 2004; Katerji et al., 2008; Vico and Porporato, 2015; Kikal and Irmak 2017) and the FAO book on crop yield response to water availability (Steduto et al., 2012).

Relevance of WUE for linking water and carbon cycles

Given this mosaic of metrics used to express water use efficiency, it is extremely important to always present units and definitions explicitly. However, regardless of the selected metric, WUE represents a fundamental descriptor of the connection between the water and carbon cycles. Several reviews and synthesis articles have analyzed WUE in the past (e.g., Steduto, 1996; Howell, 2001; Katerji et al., 2008; Medlyn et al., 2017; Hatfield and Dold, 2019), even though syntheses of its magnitude and variability collected from different data sources and across ecosystems and environmental conditions are less common. WUE expresses the tradeoff between the plant capability of assimilating carbon and producing biomass and the water cost of such an operation. This tradeoff is essential for food production anytime water represents a limited resource for crops. Indeed, increasing WUE has motivated research toward improving agronomical techniques (Hsiao et al., 2007), especially irrigation (Howell, 2001), and it has also motivated crop breeding efforts (Condon et al., 2002, 2004; Franks et al., 2015). Any amelioration of WUE would result in the production of more or equal amounts of agricultural yield or any final product using a smaller amount of water. Concurrently, WUE is a very important trait of natural vegetation and ecosystems, because a higher WUE could potentially provide a competitive advantage in periods of water scarcity (Peters et al., 2018; Hatfield and Dold, 2019; Adams et al., 2021). Furthermore, studying future changes in WUE can be of high relevance to better understand how vegetation mediates water availability in a given region and how water availability modifies carbon budgets. For instance, if variations in climatic conditions lead to an increase (or decrease) in WUE, it would mean that vegetation productivity will increase (decrease) for unmodified water consumption or that water consumption will decrease (increase) for unmodified productivity or any combination of these possibilities. If the magnitude of the change is relevant, implications for terrestrial carbon budget (Keenan et al., 2013; Frank et al., 2015) and water resource availability (Knauer et al., 2017) could be significant. Therefore, knowledge of environmental controls and physiological and biophysical mechanisms affecting WUE under current and future climatic conditions is essential for Earth System Sciences including applications in agronomy, hydrology, and carbon cycle.

WUE observations and simulations

At the leaf scale, water use efficiency (i.e., WUE_l and $iWUE$) can be measured directly by means of leaf gas exchange measurements where A_n and T are inferred by changes in CO_2 and water vapor concentrations inside a leaf chamber (e.g., Medrano et al., 2015). Another way for obtaining WUE_l is related to the isotopic composition of the leaf carbon (C). Following Eq. (3), the sole knowledge of the ratio C_i/C_a is sufficient to compute $iWUE$ as C_a is known for a given historical period. During diffusion of CO_2 through stomata and photosynthesis processes there is a quantifiable discrimination ($\Delta^{13}C$) between the lighter $^{12}CO_2$ compared to the heavier $^{13}CO_2$ stable molecules. Based only on the knowledge of plant material $\delta^{13}C_p$, i.e., the ratio of ^{13}C and ^{12}C compared to an international standard, it is possible to compute plant $\Delta^{13}C$ (Laverne et al., 2019). The quantity $\Delta^{13}C$ has been found to be related to C_i/C_a in the first products of photosynthesis (Farquhar et al., 1982; Farquhar et al., 1989) Laverne et al., 2019) and, even though methodological concerns related to the role of mesophyll conductance (Seibt et al., 2008) and forest stand dynamics (Marchand et al., 2020) could be important, in its simplest form the $\Delta^{13}C - C_i/C_a$ relation can be expressed as:

$$\Delta^{13}C = a + (b - a) \left(\frac{C_i}{C_a} \right) \quad (7)$$

where $a = 4.4\text{‰}$ is the fractioning due to CO_2 diffusion and $b = 27\text{‰}$ is the apparent fractioning by Rubisco during carboxylation (Laverne et al., 2019). Strictly speaking, Eq. (7) can be used once leaf level $\delta^{13}C$ is known. However, with some adjustment to account for post-photosynthetic fractioning, it is typically used to infer C_i/C_a , and thus $iWUE$ (Eq. 3), based on the value of $\delta^{13}C_p$ observed in the cellulose of tree-rings and represents an indirect way to reconstruct average $iWUE$ in given periods (or years) for the whole plant (Peñuelas et al., 2011; Frank et al., 2015; Adams et al., 2020).

At the ecosystem scale, water use efficiency (i.e., WUE^{eco} and $EWUE$) can be computed based on observed latent heat (ET in energy units), VPD, and inferred GPP values from eddy-covariance flux measurements above vegetation (e.g., Beer et al., 2009). To compute $EWUE^{eco}$, an estimation of canopy conductance $G_{s,can}$ is required, which is typically derived by inverting the Penman-Monteith equation (Laverne et al., 2019). Using latent heat as a measure of total water use provides lower values of WUE^{eco} compared to WUE_T^{eco} as transpiration is only a fraction of total ET. To avoid this problem, several studies filter for days and hours where ground evaporation and evaporation from interception are expected to be negligible (e.g., Keenan et al., 2013; Mastrotheodoros et al., 2017). However, a physiological interpretation of WUE^{eco} and $EWUE$ remains complex due to the uncertainty embedded in flux tower ET and GPP observations (Knauer et al., 2018). Estimates of WUE^{eco} can be also obtained from global maps of GPP and ET derived from flux-tower data by means of machine learning techniques such as FLUXCOM (Jung et al., 2020).

Spaceborne remote sensing products offer the capability to estimate WUE^{eco} from field to global scales (e.g., Xue et al., 2015). However, most remote sensing products provide very indirect estimates of GPP (or NPP) and ET, since these quantities are derived from observations of vegetation radiation reflections in different wavebands, and of outgoing thermal radiation (e.g., Zhang et al., 2019b), and effects of other environmental factors are modeled. Therefore, the remotely sensed WUE^{eco} estimates are subjected to considerable uncertainties and are largely the product of simple models applied to the original observations.

Finally, estimates of WUE^{eco} can be obtained using the results of Terrestrial Biosphere Models (e.g., [Huang et al., 2015](#)). These models mechanistically solve energy, water, and carbon budgets and thus provide all necessary quantities to compute $iWUE^{eco}$, WUE^{eco} and WUE_T^{eco} . However, these values depend on the model capability to correctly reproduce water and carbon fluxes, which are influenced by the model internal structure, with non-negligible inter-model differences in the simulations of WUE^{eco} ([Paschalis et al., 2020](#)).

Crop water productivity

Given the economic and societal importance of increasing agricultural yield and diminishing water use for irrigation, a large attention has been dedicated to improving crop water use efficiency both at leaf ($iWUE$) and field (WUE^{eco}) scale, and consequently improving $WP_{B/ET}$ and $WP_{Y/ET}$. The catchy slogan “more crop per drop” ([Kijne et al., 2003](#)) summarized this effort for improving $WP_{Y/T}$ especially through selective breeding. However, the early enthusiasm for breeding for higher water use efficiency has been questioned ([Blum, 2009](#)) for reasons detailed below. Agricultural yield (Y [$gDM\ m^{-2}\ day^{-1}$]) can be decomposed in various terms to explicitly account for $WP_{B/ET}$ or $WP_{B/T}$ ([Passioura, 1996](#)):

$$Y = B \cdot HI = T \cdot WP_{B/T} \cdot HI = ET \cdot \frac{T}{ET} \cdot WP_{B/T} \cdot HI = ET \cdot WP_{B/ET} \cdot HI \quad (8)$$

where B [$gDM\ m^{-2}\ day^{-1}$] is the produced crop biomass, HI [–] is the Harvest Index expressed as the yield divided the biomass; and by definition: $WP_{B/T} = B/T$ [$gDM\ m^{-2}\ mm^{-1}$] and $WP_{B/ET} = B/ET$ [$gDM\ m^{-2}\ mm^{-1}$]. Eq. (8) suggests that for a given amount of evapotranspired water “ET,” the yield can be improved (i) by increasing the amount of water that is used for transpiration rather than for other ET pathways, i.e., the T/ET ratio; (ii) by increasing the carbon allocation to the harvested products (e.g., grains, fruits), i.e., the HI value; (iii) by enhancing the amount of carbon acquired for unit of transpired water, i.e., $WP_{B/T}$ itself. These are the three major mechanisms also described in [Condon et al. \(2004\)](#) to improve WUE by breeding of crop varieties. A strong linearity between biomass production (and yield) in crops and transpiration has been historically observed ([Fig. 2a–c](#)) since the work of [de Wit \(1958\)](#), who reassessed biomass yield and T observations carried out in containers at the beginning of the 20th century ([Briggs and Shantz, 1913, 1914](#); [Shantz and Piemeisel, 1927](#); [Dillman, 1931](#)). These linear relationships, even though with lower correlations and significant site to site variability, have been widely confirmed in the literature (e.g., [Hanks, 1983](#)) using field measurements of yield and ET ([Fig. 2d](#)) or, better, ET divided by potential evapotranspiration (E_{POT}) ([Fig. 2e](#)). ET is used rather than T , as separating the two in the field is extremely challenging. However, assuming that a large part of the variability is due to uncertainty in field observations and lack of knowledge of T/ET , once transpiration is re-scaled with potential evapotranspiration (E_{POT}), and CO_2 effects are accounted for by rescaling C_a with a reference value C_a^* , biomass production can be expressed as ([Steduto et al., 2007](#)):

$$B = WP^* \frac{T}{E_{POT}} \left(\frac{C_a}{C_a^*} \right) \quad (9)$$

The coefficient of proportionality WP^* [$gDM\ m^{-2}\ day^{-1}$] can be assumed to be nearly constant across a range of environmental conditions for each crop type and, for a given level of mineral nutrition (e.g., [Hanks, 1983](#); [Sinclair et al., 1984](#); [Steduto et al., 2007](#)). This assumption is especially true for a given location, while variability in the B (or Y) vs T/E_{POT} relation across locations can be considerable, but still lower than the variability among different crops ([Fig. 2d](#) and [e](#)). Typically, WP^* values range from 10 to 33 $gDM\ m^{-2}\ day^{-1}$ ([Table 2](#)). For a summer potential evaporation of 5 $mm\ day^{-1}$ and Carbon Use Efficiency (e.g., NPP to GPP ratio) of 0.5, these values lead to a WUE_i of 2.0–6.6 $gC\ kg\ H_2O^{-1}$, values just slightly larger than the WUE_i obtained from gas exchange observations (see next Section). As only a fraction of GPP represents yield and not all ET is transpiration, average $WP_{Y/ET}$ for major crops are smaller (0.25–0.7 $gC\ kg\ H_2O^{-1}$) with larger values for C_4 crops ([Table 1](#)). WP^* may be reduced by nutrient limitations, particularly lack of nitrogen. For some species with high rates of metabolic respiration for oil producing seeds or expensive fruits, pre-anthesis and post-anthesis values of WP^* might differ ([Table 2](#)) with lower values occurring toward the end of the growing season ([Steduto et al., 2007](#)). From Eq. (9) it follows that for $C_a = C_a^*$:

$$WP_{B/T} = \frac{WP^*}{E_{POT}} \quad (10)$$

which also means that, for a given climate, $WP_{B/T}$ must be nearly constant, with very limited room to modify yields by acting on $WP_{B/T}$. Eqs. (8) and (10) can be also linked to the relation between yield and evapotranspiration that has been the foundation of yield response to water availability in the FAO books ([Doorenbos and Kassam, 1979](#); [Steduto et al., 2012](#)):

$$\left(1 - \frac{Y}{Y_X} \right) = K_y \left(1 - \frac{ET}{E_X} \right) \quad (11)$$

where Y_X is the maximum yield corresponding to the maximum ET, $E_X \approx E_{POT}$. Eq. (11) is a water production function and can be applied to all agricultural crops (i.e., herbaceous, trees, and vines) and describes a linear proportionality between actual ET and Y . The only parameter is a yield response factor (K_y) that captures the complex relation between crop productivity and water use by a crop, and thus summarizes many biological, physical, and chemical processes ([Steduto et al., 2012](#)). If WP^* is constant, and T/ET

Fig. 2 Agricultural yields (Y , dry matter biomass in yield) as a function of the ratio between transpiration (T) and potential evapotranspiration (E_{POT}), (a) for Wheat ($n = 20$) (b) Alfalfa ($n = 17$) and (c) Sorghum ($n = 21$). Data were summarized by [de Wit \(1958\)](#) based on the original publications of [Briggs and Shantz \(1913, 1914\)](#), [Shantz and Piemeisel \(1927\)](#) and [Dillman \(1931\)](#), where crops were grown in closed containers and the surface of the soil was sealed to prevent direct evaporation. Experiments were carried out in four different locations of the USA Great plains: Delhart (Texas), Akron (Colorado), Newell (South Dakota) and Mandan (North Dakota) in the period 1911–1922. For Sorghum data were also from Bombay (India) ([Kanitkar et al., 1943](#)). (d) Wheat yield as a function of evapotranspiration (ET) (lack of information about potential evapotranspiration during the wheat growing season precludes the possibility to use ET/E_{POT}), data are derived from eight individual studies summarized in [Vico and Porporato \(2015\)](#). (e) Maize yield as a function of the ratio between evapotranspiration (ET) and potential evapotranspiration (E_{POT}). Crops were grown under field conditions in 1974 and 1975 and they underwent various treatments modifying irrigation amount, irrigation frequency, and salinity ([Stewart et al., 1977](#)). Results are four different locations in the USA (Davis ($n = 216$, blue), Fort Collins ($n = 161$, yellow), Logan ($n = 157$, green), and Yuma ($n = 154$, red)). In all plots, we report the linear fitting and corresponding coefficient of determination R^2 .

Table 2 The water productivity WP^* [gDM m⁻² day⁻¹] coefficient for different crop types as reported in AquaCrop reference manual—Annex ([Raes et al., 2018](#)).

Crop	WP^* [gDM m ⁻² day ⁻¹]	Fractional reduction (during yield formation)
Wheat	15.0	1.0
Rice	19.0	1.0
Maize	33.7	1.0
Soybean	15.0	0.6
Barley	15.0	1.0
Sorghum	33.7	1.0
Cotton	15.0	0.7
Sunflower	18.0	0.6
Sugarcane	30.0	1.0
Potato	18–20	1.0
Tomato	18	1.0
Sugar beet	17.0	1.0
Quinoa	10.5	0.9
Tef	14.0	1.0
Dry Bean	14.0	0.9

The reference value and the fractional reduction during yield formation for each crop are reported.

and HI are the same in potential and actual conditions, then $K_y = 1.0$. Observations suggest indeed a relatively limited range of K_y values around 0.8 to 1.35 for various crops (Doorenbos and Kassam, 1979).

The fact that WP^* has been historically observed to be a conserved quantity for a given crop (Steduto et al., 2007), it implies that once differences in evaporative demand and C_a are discounted, $WP_{B/ET}$ and $WP_{Y/ET}$ are also conserved. This makes it particularly challenging to improve $WP_{B/ET}$ beyond the values already achieved with best agricultural practices. However, breeding of crop varieties that are more efficient in their water use has been shown to be possible (Condon et al., 2004). While it is relatively easy to select for genotypes with higher iWUE at the leaf scale, initial expectations of substantial water savings were not maintained at the overall plant and field scale (Medrano et al., 2015), where genotypes with higher iWUE generally had lower productivity and yields (Condon et al., 2004). This is because the iWUE increase is often obtained by lowering g_s , rather than increasing A_n (Blum, 2009), therefore growth and yield are not stimulated at the plant level. Evidence suggests that genetically modified plants may not be better able to cope with drought than selection-bred cultivars as smaller leaf area and lower g_s may decrease productivity in the field and genetic modifications may delay stress onset rather than conferring drought resistance or avoidance (Lawlor, 2013).

Additionally, other important factors such as the length of the growing season or the biomass production in the early growing phase before anthesis have been shown to affect yield more significantly than iWUE itself, complicating the approaches for improving WUE^{eco} without compromising productivity (Condon et al., 2004). Therefore, alternative strategies aiming at reducing ground evaporation and increasing photosynthesis through higher LAI could be more beneficial (Condon et al., 2004). For instance, growing crops in a less water demanding atmosphere (lower VPD) can improve WUE^{eco} . An increase in WUE^{eco} could be obtained indirectly by fertilizer application in nutrient poor soils. When nutrients are limiting, fertilizers increase GPP and yield, often without increasing ET proportionally especially in wet years or ecosystems. Soil texture has also been shown to be able to affect $WP_{Y/ET}$ with lower values in clay soils where crop root water uptake may be hindered (Katerji and Mastrorilli, 2009). More generally, improvements in WUE can be obtained by acting on agricultural practices and management (Hatfield et al., 2001). Agricultural practices, such as crop residue management, tillage, mulching, weed control, use of intercropping, are shown in certain experiments to increase water available in the root zone, WUE^{eco} and $WP_{B/ET}$ (Hatfield et al., 2001; Turner, 2004; Hatfield and Dold, 2019). However, experiments with various agricultural practices have also shown a decrease or lack of response in $WP_{B/ET}$ (Hatfield et al., 2001). Differences among studies and difficulty in reproducing certain positive responses suggest that results are likely climate and crop specific and are also affected by the specific conditions of the experiment. Other practices such as crop row spacing and use of appropriate irrigation practices have also shown improvements in $WP_{B/ET}$. Specifically, plant spacing modifies the plant radiation environment and photosynthetically active radiation absorption, whereas irrigation might remove water stress, improving overall $WP_{B/ET}$. Techniques such as drip irrigation can minimize ground evaporation and evaporation from interception, therefore increasing the T/ET ratio and $WP_{B/ET}$ even further. In summary, management techniques acting on nutrient availability, irrigation application, water retention in the root zone, root water uptake, soil evaporation, and the biomass allocation toward the yield part of the crop are the best leverages to improve $WP_{Y/ET}$ (Hsiao et al., 2007) as they mostly act upon T/ET and HI.

WUE variability and environmental dependencies

It is often textbook knowledge that, at the leaf scale, plants in dry environments have higher WUE to cope with limited water availability (e.g., Chapin et al., 2002, p. 114). Concurrently, C_4 plants have lower C_i/C_a and higher WUE_i than C_3 plants because of their capability of avoiding photorespiration losses and attaining higher photosynthetic rates for a given C_a . Observations from recently compiled global databases of leaf-level gas exchange (Lin et al., 2015; Medlyn et al., 2017) and tree-ring isotope data (Adams et al., 2020) do not support a considerable climate dependence of iWUE. iWUE observations clearly suggesting that the C_4 photosynthetic pathway confers a considerably higher iWUE, while C_3 grasses and crops have the lowest iWUE values. iWUE values range from 21 to 151 $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ H}_2\text{O}$ (5–95 quantile) or 21–102 if we exclude C_4 plants (Fig. 3a), indicating that iWUE and C_i/C_a differ among C_3 and C_4 species. A somewhat smaller range of iWUE, 33–80 $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ H}_2\text{O}$ (5–95 quantile), is obtained from tree-ring isotope analysis, consequent on the database containing more values but only C_3 species, as it is limited to trees (Fig. 3b). Leaf-level iWUE correlation with WUE_i is small ($r^2 = 0.12$) (Fig. 3c), demonstrating an important role for the VPD conditions at which measurements are carried out. Leaf-level WUE_i range is 1.8–6.4 $\mu\text{mol CO}_2 \text{ mmol}^{-1} \text{ H}_2\text{O}$ (5–95 quantile) [corresponding to 1.2–4.2 $\text{gC kg H}_2\text{O}^{-1}$], with strong overlaps among plant functional types, where only evergreen needleleaf species show substantially higher WUE_i values (Fig. 3d). It must be noted, however, that Crassulacean Acid Metabolism (CAM) plants, that keep their stomata open at night when VPD is lowest and not during the daytime, can reach WUE_i values of 4–20 $\mu\text{mol CO}_2 \text{ mmol}^{-1} \text{ H}_2\text{O}$, much higher than for other species (Lambers and Oliveira, 2019, p. 243). These are not represented in Fig. 3. The most striking observation in Fig. 3 is, however, the large overlap of iWUE and WUE_i values across different plant functional types, showing that different iWUE values might co-exist in the same biome and, concurrently, that different biomes might have very similar average iWUE. Leaf-scale and tree-ring iWUE show a very weak negative dependence ($r^2 = 0.032$ and $r^2 = 0.076$ respectively) with precipitation, with fitting curves (C_3 species only) largely overlapping for precipitation lower than 2000 mm yr^{-1} (Fig. 3b), thus not supporting the hypothesis that on average plants in arid and semiarid biomes use water considerably more efficiently, than in other climates.

Overall, iWUE variability among C_3 species spans less than a factor of five and, in total, a factor of seven, which likely represents the leaf physiological and morphological flexibility in controlling iWUE, similar to the factor of seven derived from theoretical expectations (Eq. 3). This is also reflected in the values of the estimated C_i/C_a ratio, considerably lower for C_4 species (0.29–0.73)

Fig. 3 (a) Boxplot of iWUE computed from the maximum values of net assimilation A_{max} and stomatal conductance $g_{s,max}$ of a given species for different biomes (ENF, evergreen needleleaf forest; EBF, evergreen broadleaf forest; DBF, deciduous broadleaf forest; TRF, tropical rainforest; SAV, savannah; SHB, shrub; C3G, C3 grass; C4G, C4 grass; C3C, C3 crops). Data are from the Lin et al., 2015 database (53 sites –155 species-sites, as species-sites with less than 4 observations have been excluded). (b) Scatter plot between iWUE and local average annual precipitation in the Lin et al., 2015 database (53 sites –155 species-sites) subdivided in C₃ and C₄ species and in the Adams et al., 2020 database (181 sites –362 species-sites, iWUE values are averaged of the time series). Precipitation is extracted from the GPCC version 2020 database (<https://www.dwd.de/EN/ourservices/gpcc/gpcc.html>) based on site latitude and longitude. Second order polynomials are used to fit the data for C₃ species. (c) Scatter plot between WUE_i and iWUE computed from A_{max} and $g_{s,max}$. (d) Boxplot of WUE_i for different biomes computed as the mean of net assimilation divided transpiration for each species-site. (e) Boxplot of $C_i/C_a for different biomes computed as the mean for each species-site starting from iWUE values.$

than for C₃ (0.55–0.86) (0.53–0.83 using data from Adams et al., 2020) but showing a substantial overlap among different biomes and slightly lower values for evergreen broadleaf and needleleaf species (Fig. 3e). Variations in average iWUE across different biomes are indeed substantially smaller than across species and reasonable differences are more within a factor of two rather than five or seven (Fig. 3a).

The magnitude of multi-annual WUE^{eco} at the ecosystem scale can be inferred from flux tower observations (Fluxnet 2015 synthesis¹) and remote sensing products (MODIS ET and GPP²). Flux tower derived WUE^{eco} range is $0.63\text{--}4.50\text{ gC m}^{-2}\text{ mm}^{-1}$ (5–95 quantile), providing a slightly larger magnitude of variability in WUE^{eco} than the leaf-level WUE_i and confirming that biomes are not an important determinant of WUE^{eco} (Medlyn et al., 2017). The weak correlation between WUE^{eco} and precipitation rather suggests that water limited sites have lower and not higher WUE^{eco} (Fig. 4a). However, this does not necessarily imply a decrease in leaf-level WUE_i as ET rather than T is used to compute WUE^{eco} , and a decreasing T/ET ratio in low precipitation regions would lead to a decrease in WUE^{eco} even with unchanged WUE_i .

The range of WUE^{eco} derived from MODIS remote sensing products is quite similar but with lower maxima, $0.62\text{--}3.96\text{ gC m}^{-2}\text{ mm}^{-1}$ (5–95 quantile for areas with precipitation larger than 50 mm yr^{-1}), than the one obtained from flux towers (Fig. 4c), but it also indicates the weak dependence on precipitation. The global maps of WUE^{eco} derived from FLUXCOM product (obtained through a machine learning extrapolation of flux tower data using various covariates, Jung et al., 2020) and MODIS tend to agree on the patterns of WUE^{eco} over temperate regions of North America, Europe, Asia, and over equatorial tropical

Fig. 4 (a) Scatter plot between WUE^{eco} and precipitation computed from the Fluxnet 2015 database (123 Sites) for different levels of Gross Primary Production (GPP). (b) Global map of WUE^{eco} computed from GPP and ET obtained from the FLUXCOM product, period 1980–2013. Reported values are the average WUE using the ANN, MARS and RF algorithms for GPP and the MLM algorithm for ET. All products used the RS + METEO data sets developed using meteorological forcing from CRUNCEP. (c) Density plot of WUE^{eco} as a function of precipitation computed from MODIS GPP and ET products. (d) Global map of WUE^{eco} computed from the MODIS GPP and ET products, period 2000–2016.

regions, but they show contrasting patterns in various semiarid regions such as Sahel, central Australia, East India and Pakistan (Fig. 4b and d). In these regions, MODIS WUE^{eco} is at the maximum, while FLUXCOM WUE^{eco} has very low values (see also Sun et al., 2016). Local flux-tower observations and process-based models (Sun et al., 2016) support low values of WUE^{eco} in semi-arid and arid regions. This evidence suggests that MODIS algorithms might be particularly problematic in approximating ET and/or GPP in regions with sparse vegetation. While the pattern of FLUXCOM derived WUE^{eco} appears more realistic, the maximum values rarely exceed 3.0 gC m⁻² mm⁻¹ (0.25–2.05, the 5–95 quantile) in contrast with local flux-tower observations and process-based model results (Sun et al., 2016), which report values above 4.0 gC m⁻² mm⁻¹. The FLUXCOM product also provides very gradual spatial variability in WUE^{eco}. These patterns are likely the result of a smoothing, induced by the machine learning algorithm and of the 0.5° spatial scale of the FLUXCOM product (Fig. 4b). Overall, FLUXCOM information suggests that peaks of WUE^{eco} are obtained in moist tropical forests and in forests at the border between temperate and boreal climates in Russia and Canada. In these regions water stress is likely minimal and atmospheric water demand moderate, with both factors allowing plants to take full advantage of the available water to assimilate carbon, and compounding effects are related to dense canopies with a high LAI. Increasing IWUE with higher soil moisture and larger LAI have been observed across flux tower sites (Beer et al., 2009), which supports this assessment.

Regions which are either strongly temperature-limited, such as arctic and sub-arctic regions, or strongly water-limited, such as semi-arid and arid regions and characterized by deserts and sparse vegetation (e.g., south-west USA, central Asia, south Africa, central Australia) have a considerably lower WUE^{eco}. In these regions, vegetation is not able to use water to assimilate carbon at the highest capacity, either because other factors (e.g., temperature, light) are limiting or because soil and atmospheric water limitations themselves decrease GPP. The vegetation in these regions cannot attain a dense cover with high LAI. These patterns have been confirmed by process-based models (Sun et al., 2016) and by studies estimating global WUE^{eco} with alternative methodologies (Cheng et al., 2017).

Simulations with the mechanistic terrestrial biosphere model T&C (Fatichi et al., 2016; 2021) for 119 sites characterized by different climates and biomes support the weak dependence of multi-annual WUE^{eco} on precipitation, showing lower WUE^{eco} values in semiarid regions, even though with a large scatter, in agreement with the FLUXCOM product (Fig. 5a). The WUE^{eco} range

Fig. 5 Scatter plot of ecosystem scale (a) WUE^{eco} and (b) WUE_T^{eco} as a function of annual precipitation computed with the terrestrial biosphere model T&C for 119 sites characterized by different climates and biomes. (c) Scatter plot between GPP and transpiration divided potential evapotranspiration (T/E_{POT}) for the same 119 sites. A fitting linear function, without intercept, $GPP = 4080 (T/E_{POT})$ [$gC\ m^{-2}\ year^{-1}$] ($r = 0.77$) is also illustrated in panel c (dashed line).

of $0.9\text{--}3.5\ gC\ m^{-2}\ mm^{-1}$ (5–95% percentile) is also very similar to the ones obtained from flux-towers and other process-based models (Sun et al., 2016) with a median value of $2.33\ gC\ m^{-2}\ mm^{-1}$ demonstrating that ecosystem scale WUE^{eco} variability (a factor of 4) is not too dissimilar from variability at the leaf scale. Mechanistic terrestrial biosphere models allow analysis of WUE_T^{eco} , which is a quantity that cannot be easily derived from observations. Model simulations with T&C shows that the patterns of WUE^{eco} are largely preserved using WUE_T^{eco} even though WUE_T^{eco} values are larger ($1.3\text{--}5.4\ gC\ m^{-2}\ mm^{-1}$), as expected (Fig. 5b). These values compare well with the observed instantaneous WUE_i of $1.2\text{--}4.2\ gC\ m^{-2}\ mm^{-1}$, showing that canopy and ecosystem upscaling and long-term averaging are not generating any major departure from the magnitude of the fundamental leaf physiological process. This also suggests that the variability of WUE_i observations across species and environmental forcing is sufficient to cover a quite large range of natural conditions, representative of various canopies, ecosystems, climates, and soils.

Simulations also confirm a considerable scatter of WUE_T^{eco} values, increasing with precipitation ($r = 0.48$, $P < 0.001$) and decreasing with temperature ($r = -0.24$, $P = 0.007$, not shown), while the negative correlations with radiation ($r = -0.64$, $P < 0.001$) and VPD ($r = -0.59$, $P < 0.001$) are much stronger (not shown), reinforcing the idea of WUE^{eco} and WUE_T^{eco} mostly decreasing with increasing evaporative demand, and increasing with higher atmospheric CO_2 (e.g., Eq. 9). Note, however, that these are spatial patterns in WUE^{eco} observed across sites and might differ from temporal environmental dependencies of WUE^{eco} at a given site. In this regard, studies across the US found that WUE^{eco} is sensitive to VPD (Novick et al., 2016) and, for a given site, flux-tower observations have shown that $iWUE^{eco}$ increases with increasing VPD for different levels of soil moisture, at least as far as VPD does not exceed $2\text{--}3\ kPa$ (Zhang et al., 2019a). A similar pattern is also observed in $iWUE$ from leaf-scale observations with $iWUE$ increasing with VPD up to $3.5\ kPa$ and decreasing thereafter (not shown). A normalization of transpiration with potential evapotranspiration, similar to what is commonly done for crops, does lead to a much stronger correlation with GPP ($r = 0.77$, $P < 0.001$) in T&C simulations (Fig. 5c). The derived multi-site $WP^* = 11\ gDM\ m^{-2}\ day^{-1}$ (assuming a biomass conversion efficiency of 50%) is on the lower end of values published for crops.

In semi-arid regions WUE_T^{eco} tends to decrease following WUE^{eco} , as the T/ET ratio in the simulations does not depend on precipitation or aridity (Paschalis et al., 2018), confirming that vegetation adapted to arid and semi-arid regions is not able to use water more efficiently than other biomes at the ecosystem scale and over annual and multi-annual scales, contrary to common expectations. However, an increase of $iWUE$ with aridity has been shown, even though with very weak correlation, using $iWUE$ inferred from tree rings (Adams et al., 2021). Large values of WUE^{eco} ($2.15\ gC\ m^{-2}\ mm^{-1}$) for the corresponding aridity level (only $280\ mm$ of precipitation) have been also reported for the Yatir forest in Israel (Helman et al., 2017). This might suggest that WUE of trees growing in arid regions might behave differently from grassland and shrubland ecosystems.

Looking in time rather than space, $iWUE$ has been inferred to increase in response to extreme droughts at the regional scale based on inversion of atmospheric isotopic composition (Peters et al., 2018). However, this can be an indirect effect of increasing VPD values. Another study showed contrasting patterns of WUE^{eco} response to drought conditions, with WUE^{eco} increasing with drought in arid ecosystems and decreasing in semi-arid/sub-humid ones (Yang et al., 2016). An important point is that WUE^{eco} and $iWUE$ can exhibit seasonal variations linked to climate seasonality and leaf phenology (e.g., Zhu et al., 2014). Additionally, simply referring to their definitions, WUE^{eco} and $iWUE$ are expected to exhibit diverging responses to increasing VPD associated with periods of soil or atmospheric water stress. $iWUE$ increases during atmospheric droughts, as transpiration response to VPD is sub-linear, and the opposite should occur for WUE^{eco} as the rate of change of ET is expected to be less than that for GPP.

(Zhang et al., 2019a). Responses to decreasing soil moisture are likely more complex and non-monotonic, as iWUE might increase for moderate water limitations, where transpiration is more sensitive than A_n to low levels of soil moisture. Then iWUE can decrease to nearly zero or even negative values ($A_n < 0$ in Eq. 2) when soil moisture completely limits photosynthesis, but some residual transpiration still occurs. However, given the species-to-species variability and the multiple factors controlling ecosystem scale ecohydrological dynamics, a full characterization of WUE responses to atmospheric water limitations and droughts remains an open question.

Other studies have investigated the interactions between WUE and meteorological forcing, such as wind (Schymanski and Or, 2016) and increasing aerosol concentrations (Gao et al., 2018), with WUE decreasing when direct radiation is stronger due to a cleaner atmosphere, and increasing with higher wind speed at the leaf scale.

Stomatal conductance modeling and WUE

The simulated WUE^{eco} in terrestrial biosphere models is a result of upscaling processes from the leaf to the canopy and to the entire ecosystem (Medrano et al., 2015; Medlyn et al., 2017). Yet, the parameterization of leaf-level stomatal conductance represents an essential component of the simulated iWUE and WUE^{eco} in these models. Mechanistic descriptions of leaf-level stomatal conductance and transpiration have been proposed (Buckley, 2019), however, they require many parameters difficult to determine for ecosystem scale applications. Therefore, in terrestrial biosphere models, parameterizations of stomatal conductance (g_s) as a function of A_n are often based on semi-empirical expressions such as Ball-Berry—Eq. (12) (Ball et al., 1987) or Leuning—Eq. (13) (Leuning, 1995) or expressions derived from stomatal conductance optimization approaches, including Medlyn—Eq. (14) (Medlyn et al., 2011). Each equation is formulated slightly differently, but they all contain a key parameter (m [–], a_1 [–] and g_1 [kPa^{0.5}], respectively) that controls iWUE:

$$g_s = g_0 + m \cdot A_n \frac{R_H}{C_s} \quad (12)$$

$$g_s = g_0 + a_1 \cdot \frac{A_n}{(C_{s/i} - \Gamma) \left(1 + \frac{VPD}{D_0}\right)} \quad (13)$$

$$g_s = g_0 + \left(1 + \frac{g_1}{\sqrt{VPD}}\right) \frac{A_n}{C_a} \quad (14)$$

where g_0 [$\mu\text{mol CO}_2 \text{ m}^{-2} \text{ leaf s}^{-1}$] represents the residual stomatal conductance at zero net assimilation due to cuticular conductance and imperfect stomatal closure (Duursma et al., 2019). C_a , C_s , C_i [ppm] are the CO_2 concentrations in the atmosphere, leaf surface, and leaf interior, R_H [–] is the relative humidity, Γ [ppm] is the CO_2 compensation point, VPD [kPa] is theoretically computed from leaf temperature (but more often using air temperature) and assuming vapor saturated conditions inside the leaf, and D_0 [kPa] is an empirical parameter modulating VPD response in Eq. (13).

Parameters m , a_1 , and g_1 are inversely proportional to iWUE. In early models, only two (or three if conifers were separated) values of m ($m = 9$ for C_3 , and $m = 4$ for C_4 plants) were assumed (Sellers et al., 1996) as a corollary of the assumption that C_i/C_a should have been constant within C_3 and C_4 plants. However, now we know that their values change across species and biomes (Lin et al., 2015; Medlyn et al., 2017; Miner et al., 2017) and potentially also over time (Lammertsma et al., 2011; Mastrotheodoros et al., 2017), with important implications for modeling iWUE and WUE^{eco} . An estimate of the values of a_1 and g_1 is obtained from the global leaf scale gas exchange database (Lin et al., 2015) and it shows the strong inverse correlation between those parameters and iWUE ($r^2 = 0.65$ and $r^2 = 0.67$, respectively for a power-law fitting) (Fig. 6a and b) and the very tight correlation ($r^2 = 0.96$) between the two parameters (Fig. 6c). This suggests that both Eq. (13) and Eq. (14) might provide very similar responses in terms of WUE once properly parameterized. Using the dataset compiled by Lin et al. (2015), the estimated range of g_1 is 1.1 to 7.6 (5–95 percentile), and with $D_0 = 1$ kPa, a_1 ranges from 2.6 to 15.0, providing a variability in the order of 5–7 times, in line with the variability in WUE_l and iWUE themselves. The ranges provided here are relevant for realistic parameterizations of terrestrial biosphere models.

Trends in water use efficiency

According to Eq. (3), iWUE should increase linearly with C_a if the C_i/C_a ratio remains constant with varying C_a , as indicated by physiological literature (e.g., Morison, 1985; Drake et al., 1997) and process-based modeling (Fig. 7a). Stomatal conductance, indeed, generally decreases with C_a (Fig. 7b, Medlyn et al., 2001). The increase in iWUE at the leaf and plant scale with C_a has been widely documented, (e.g., Wullschlegel et al., 2002) but the magnitude of reported WUE increments with C_a has varied significantly in the literature (Walker et al., 2021). Part of this spread is related to methodological differences in various studies, but part is also due to different analyzed periods as C_a changed through time. Once we normalized published results on a per unit of CO_2 change (ppm^{-1}), the observed increase in iWUE seems to be constrained between 0.2% and 0.5% $\text{ppm}^{-1} \text{ CO}_2$, which is aligned with or larger than theoretical expectations of a 0.26% $\text{ppm}^{-1} \text{ CO}_2$ increase in the last 20 years (Fig. 7c). Although iWUE has increased more

Fig. 6 Scatter plot between $iWUE$, computed from the maximum values of net assimilation $A_{\max}$ and stomatal conductance $g_{s,\max}$ for each species using (a) the parameter a_1 of the Leuning model of stomatal conductance and (b) the parameter g_1 of the Medlyn model of stomatal conductance. The parameters are fitted to the single leaf-gas exchange observations in the database of Lin et al. (2015) and then averaged for species-sites (53 sites and 155 species/sites). (c) Scatter plot between the a_1 and g_1 parameters.

Fig. 7 (a) Leaf scale WUE_i , and (b) stomatal conductance g_s , as a function of atmospheric CO_2 concentration (C_a). Results are obtained with the T&C model for optimal meteorological conditions and realistic parameters for a C_3 and C_4 plants. (c) Expected changes in $iWUE$ [$\% \text{ ppm}^{-1} \text{ CO}_2$] or [$\% \text{ year}^{-1}$] in the period 1860–2020, assuming a constant ratio C_i/C_a , changes in [$\% \text{ year}^{-1}$] are smoothed with a 15-year moving average (orange line).

in $\% \text{ year}^{-1}$ in recent decades as C_a increased with time, the opposite is true for $iWUE$ sensitivity to CO_2 [$\% \text{ ppm}^{-1} \text{ CO}_2$], which decreases as C_a grows (Fig. 7c). More specifically, estimates based on the isotopic content of tree rings suggest that $iWUE$ increased by $0.20\% \text{ ppm}^{-1} \text{ CO}_2$ between 1850 and 2000 in 53 sites worldwide (Leonardi et al., 2012) and $0.27\text{--}0.31\% \text{ ppm}^{-1} \text{ CO}_2$ in 1100 tropical trees (van der Sleen et al., 2015). Other studies found larger trends of $0.46\% \text{ ppm}^{-1} \text{ CO}_2$ (Saurer et al., 2004), $0.44\% \text{ ppm}^{-1} \text{ CO}_2$ (Saurer et al., 2014), $0.41\% \text{ ppm}^{-1} \text{ CO}_2$ (Peñuelas et al., 2011), $0.38\% \text{ ppm}^{-1} \text{ CO}_2$ (Mathias and Thomas 2021), $0.22\% \text{ ppm}^{-1} \text{ CO}_2$ for broadleaf and $0.35\% \text{ ppm}^{-1} \text{ CO}_2$ for conifer trees in Europe (Frank et al., 2015), and a median $0.37\% \text{ ppm}^{-1} \text{ CO}_2$ was

reported during the last 40 years (Silva and Anand, 2013). Analysis of atmospheric CO₂ isotope data also supports an increase in the ¹³C/¹²C isotopic discrimination of land photosynthesis, which suggests a global increase in iWUE during the 20th century of 0.28% ppm⁻¹ CO₂ (Keeling et al., 2017), proportional to the C_a increase. A study using tree ring isotopes show that iWUE sensitivity to CO₂ has considerably declined with iWUE trends decreasing from 0.75% ppm⁻¹ CO₂ to 0.30% ppm⁻¹ CO₂ throughout the 21st century, pointing to a necessary positive trend in C_i/C_a to explain the result (Adams et al., 2020). The computed sensitivity in the early century appears very large in comparison to theoretical expectations and other studies and have been indeed revised to lower values based on new knowledge of mesophyll conductance, which points to minor changes in C_i/C_a (Gong et al., 2022).

CO₂ enrichment experiments such as the Duke and ORNL Free-Air Carbon dioxide Enrichment experiments (FACE) also show a clear increase in ecosystem-scale WUE measured as net primary production over transpiration with changes of 0.15% ppm⁻¹ CO₂ and 0.20% ppm⁻¹ CO₂ for Duke and ORNL, respectively (De Kauwe et al., 2013). These values are on the low-side of tree-ring derived increase in iWUE, but are obtained from forest scale observations with abrupt CO₂ enrichments.

Trends in IWUE can also be estimated using eddy covariance observations of carbon, water, and energy fluxes between the land surface and the atmosphere, although with noticeable uncertainties (Knauer et al., 2018). Using eddy covariance observations, Keenan et al. (2013) detected a large 1.23% ppm⁻¹ CO₂ increase in IWUE across forest sites in the Northern Hemisphere. This increase was surprising as it is more than five times larger than the theoretically expected trend and much larger than trends observed in tree rings and FACE experiments (Medlyn and De Kauwe, 2013). The result prompted other authors to conclude that the observed changes in IWUE should be explained by variables other than C_a and that trends of this magnitude are not a large-scale phenomenon (Knauer et al., 2017). A subsequent study with longer and updated flux tower data reassessed this trend at 0.58% ppm⁻¹ CO₂ (Mastrotheodoros et al., 2017), and model attribution showed that roughly 1/3 of this trend was due to air temperature and VPD effects and the rest explained by changes in C_a and potentially plant trait plasticity—driven by environmental changes and reflected in trends in plant functional traits including, but not limited to, the sensitivity of reference stomatal conductance to CO₂ (e.g., the a₁, g₁, or m parameter).

Terrestrial biosphere model analyses at global scale also report IWUE increases to the order of 0.18–0.21% ppm⁻¹ CO₂ for the 21st century (Ito and Inatomi, 2012; Huang et al., 2015). An analytical WUE model for global terrestrial ecosystems developed by directly upscaling WUE_i globally provided a 0.41% ppm⁻¹ CO₂ trend in WUE^{eco} in the period 1982–2011 (Cheng et al., 2017) with the increase in WUE^{eco} positively related to rising CO₂ concentration and increased canopy LAI, and negatively influenced by increased VPD. More recently, Ueyama et al. (2020) used a global network of flux tower observations combined with a modeling approach, to quantify the sensitivity of GPP and ET to rising C_a during 1990–2014 and estimated an iWUE^{eco} trend of 0.20% ppm⁻¹ CO₂ a little smaller than previous estimates. A study combining different data streams, i.e., tree rings, eddy covariance, and atmospheric observations reported an overall increase in WUE^{eco} of 0.52% ppm⁻¹ CO₂ between 1900 and 2010 (Dekker et al., 2016).

Remote sensing observations also provided spatial patterns of WUE^{eco} trends. Global trends vary in the order of –0.13 to +0.073% ppm⁻¹ CO₂ over the 2000–2013 period (Tang et al., 2014; Xue et al., 2015), which are however at odds with all the other estimates, and they are highlighting the problem of assessing WUE temporal and spatial variability by using remote sensing of vegetation products.

Summary

The capacity of a plant to acquire or store carbon for a given amount of water transpired can be quantified with several metrics that express a water use efficiency (or water productivity, as it is often called for crops). These metrics are fundamental to understand and properly quantify the linkage between the water and carbon cycles and for agronomic purposes. Theoretical considerations suggest that the intrinsic water use efficiency (iWUE) should be constant if C_i/C_a does not vary across species, or more realistically to have a variability in the order of five to seven times when C_i/C_a varies. This half-order of magnitude variability is confirmed by leaf-level gas exchanges, tree ring isotope, and ecosystem scale observations. It also represents a plausible range of variability for essential WUE parameters in the representation of stomatal conductance in terrestrial biosphere models. However, for a given species, long-term iWUE is rather constrained and repeated evidence from agronomy suggests a conservative value of water productivity WP_{B/T} for a given crop once CO₂ and potential evapotranspiration effects are considered. Such a conservative water productivity poses challenges for enhancing agricultural yields by breeding for higher iWUE and it rather suggests that management and improvements of T/ET and HI should lead to higher yields for unit of water used rather than changes in iWUE. In natural vegetation, eddy covariance flux observations and mechanistic modeling reproduce similar patterns of WUE^{eco} with a relatively weak positive dependence of WUE^{eco} on precipitation. These data especially disprove the intuitive thinking that water limited ecosystems should use water more efficiently. Values of WUE^{eco} are indeed generally smaller in arid and semi-arid regions and mechanistic modeling suggests that WUE_T^{eco} is likely lower too. Across sites, WUE^{eco} is negatively correlated with air temperature and solar radiation or, more generally, with potential evapotranspiration as known to occur for crops. At leaf-level and single sites, however, iWUE and IWUE have been shown to be positively correlated with VPD, at least for non-extreme VPD levels. Remote sensing derived WUE values are instead providing different WUE^{eco} patterns in semiarid regions questioning the robustness of their GPP or ET estimates in these sparsely vegetated ecosystems. Finally, multiple literature sources demonstrate that iWUE and IWUE increase with C_a at rates generally larger than the 0.26% ppm⁻¹ CO₂ derived from theoretical expectations. This suggests that other environmental controls (e.g., VPD, air temperature), ecosystem dynamics or plasticity in plant traits might have contributed to the larger than

expected increase of IWUE over the last few decades. While a C_a driven trend in WUE^{eco} will very likely persist in the future, the continuation of the positive feedbacks on the WUE^{eco} trend is less certain with iWUE sensitivity to C_a , which might already be decreasing with time. The continuation of such a strong positive trend in WUE^{eco} , however, might be essential as it affects the trade-offs between carbon uptake and water availability from local to global scales.

Abstract

The ability of plant roots to extract water from the soil at the rate required to sustain the transpiration rate is constrained by the soil hydraulic conductivity. As soils dry, their hydraulic conductivity decreases by several orders of magnitude and the root water potential required to drive soil water flow rapidly drops. Eventually, the soil can no longer sustain the transpiration rate. Plants have multiple strategies to cope with soil hydraulic limitations: besides stomatal regulation, plants alter the hydraulic properties of the rhizosphere by secreting viscous compounds, growing hairs and hosting mycorrhiza.

Key points

- Water loss from leaves creates a potential gradient in the plant that drives water uptake from soil.
- Stomata regulate the rate of water loss from leaves.
- At high rates of water loss from leaves, the rate of water movement to roots through soil can be the limiting factor of transpiration.
- Roots can increase the rate of water capture from soil by improving root-soil contact, secreting compounds or by associations with mycorrhizal fungi.

Introduction

The uptake of soil water by roots is driven by water losses from the leaves into the atmosphere. Plants are big movers of water and understanding the factors controlling root water uptake is necessary for properly modelling and predicting water exchange between the soil and the atmosphere. Root water uptake is driven by a gradient in water potential across the soil-plant-atmospheric continuum. Water evaporates from the leaves into the atmosphere across stomata. The transpiration rate depends on the difference in vapor pressure between stomata and the atmosphere (also referred to as vapor pressure deficit or VPD) and on the canopy conductance. The latter depends on stomatal conductance (which plants can regulate at short time scale) and boundary layers.

The water loss from the leaves generates a decrease in leaf water potential that passively drives the water from the soil, into the roots, along the xylem, and finally to the stomata. The gradients in water potential that drive water along this pathway depend on the hydraulic conductivities of key elements: the soil, the rhizosphere (soil in vicinity of and affected by roots), the root-soil interface, the roots (including its radial and axial components and their arrangement along the root architecture), and the xylem up to the leaves. All these conductivities are variable and are affected, to a different extent, by water potential.

In this chapter, we focus on the conductivity of the soil, of the root, and of the mycorrhizosphere (Fig. 1). Particular attention is dedicated to the water flow across the rhizosphere, which is defined as the soil in the vicinity of and affected by roots (i.e., a few mm around the roots). Large gradients in water potential occur across the rhizosphere in dry soil with low conductivity and eventually trigger stomatal closure. Plants have mechanisms to mediate these gradients by growing root hairs, symbiosis with mycorrhizae or by altering the rhizosphere hydraulic properties, such as mucilage secretion. After a short review of water flow in soil and roots, we discuss physical and biological mechanisms shaping water flow across the rhizosphere and the impact of root hairs, mycorrhiza and mucilage on root water uptake.

Principles of water flow from the soil into the roots

Soil water flow

Soil water fluxes are driven by gradients in soil water potential. In soils, the water potential [hPa] is made of three components: gravimetric (ψ_g), matric (ψ_m) and osmotic (ψ_o) potentials, with the latter not affecting water flow in soils. Volumetric soil water content θ [$\text{m}^3 \text{m}^{-3}$] and matric potential ψ_m are related through a function called the soil water retention curve. The amount of plant available water in a soil depends on typical points of this retention function (field capacity and wilting points) and on the plant root depth. Soil water holding capacity provides a buffer for plants to endure dry spells and is an important bulk soil characteristic in the long term (days-weeks). Typical values for soil water holding capacity range between 4% and 30%.

Besides its ability to store water, soil is also characterized by its ability to conduct water, called soil hydraulic conductivity $k(\theta)$ [m s^{-1}]. This is a highly nonlinear function of water content because not only do the number of wet pores decrease with water content, but also their diameter, and thereby the resistance that water has to overcome to flow. In addition, smaller pores are often more tortuous and less connected. The soil conductivity curve controls soil water fluxes within the soil profile and toward roots. In the rhizosphere, the role of the soil hydraulic conductivity is crucial as it generates an important resistance when the soil dries out.

The soil water flux is a function of the soil water potential gradient, which is described by the Buckingham-Darcy equation:

$$q = -k(\theta) \left(\frac{\partial h}{\partial x} + \frac{\partial z}{\partial x} \right) \quad (1)$$

where $\mathbf{x}$ is the position vector ($\mathbf{x} = [x, y, z]$) [m], the matric head is $h = \frac{\psi_m}{\rho g}$ [m], ρ is the water density [kg m^{-3}] and g is the gravitational acceleration [m s^{-2}].

The transfer of water within a soil profile is governed by the Richardson-Richards equation, which in three dimensions is expressed as:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial \mathbf{x}} \left[k(\theta) \left(\frac{\partial h}{\partial \mathbf{x}} + \frac{\partial z}{\partial \mathbf{x}} \right) \right] - S \quad (2)$$

where t is time [s] and S is the sink term corresponding to the volumetric root water uptake ($S > 0$) or release ($S < 0$) [$\text{m}^3 \text{m}^{-3} \text{s}^{-1}$]. The sink term in Eq. (2) represents the net uptake per volume of soil, V [m^3]. In the literature, two different approaches have been proposed for estimating S . Some authors define S as a function of macroscopic volumetric properties like root length density or soil

water status like matric potential or matric flux potential (van Lier et al., 2006). On the other hand, microscopic approaches compute S from an explicit simulation of the segment root water uptake:

$$S = \frac{\sum_i j_{r,i} A_i}{V} \quad (3)$$

where $j_{r,i}$ [m sec^{-1}] is the root water uptake per root surface (A_i) of a root segment i ($i = 1:n$) located within the soil volume V . In such a case, j_r must be explicitly calculated for each root segment between bulk soil and root xylem and will be a function of the hydraulic conductance in the rhizosphere K_{rh} [$\text{m s}^{-1} \text{MPa}^{-1}$] and in the root radial pathway K_r [$\text{m s}^{-1} \text{MPa}^{-1}$]:

$$j_r = \frac{1}{\frac{1}{K_{rh}} + \frac{1}{K_r}} (\psi_b - \psi_x) \quad (4)$$

where ψ_b and ψ_x are the water potential (including all the three components: gravimetric, matric/hydraulic and osmotic) in the bulk soil and the root xylem, respectively [MPa].

Calculating K_{rh} can be extremely challenging given the complex nature of the rhizosphere and the different possible pathways for water between the bulk soil and the root surface. Different pathways have been identified: the matrix pathway, i.e., through the soil pores, the root hair pathway, and the mycorrhiza pathway. The two latter pathways will be further developed in the last sections.

The flow through the soil matrix is obtained by solving the Richardson-Richards equation axisymmetrically, by considering the concentric flux of water from the bulk soil to the root surface (and neglecting gravity):

$$\frac{\partial \theta}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left[rk(\theta) \left(\frac{\partial h}{\partial x} \right) \right] \quad (5)$$

where r is the radial coordinate [m]. Numerous authors have provided semi-analytical solutions to this equation under steady-state ($\partial \theta / \partial t = 0$) or steady rate ($\partial \theta / \partial t = \text{constant}$) using the flux matric potential approach (van Lier et al., 2006). One important aspect of these solutions is that the soil resistance to water flux becomes a function of the water flux itself. An increase of transpiration demand generates a lower water potential at the root interface, which decreases the hydraulic conductivity in the soil. Solving Eq. (5) using steady rate conditions allows calculating an effective rhizosphere conductance K_{rh} for varying j_r (Fig. 2).

In addition to the conductivity drop, rhizosphere matric conductance also depends on the contact between the root surface and the liquid phase. If the contact between root and the liquid phase decreases, water uptake concentrates on a narrow part of the root-soil interface and further increases the conductivity drop. When the soil dries, soil and roots may shrink and adversely affect the partial contact between soil and roots. For example, Faiz and Weatherley (1982) found that the roots of sunflowers shrank by 25% when the leaf water potential dropped to around -1.5 MPa. These observations suggest that under soil drying conditions, the contact between roots and their surrounding soil is reduced due to root and soil shrinkage, decreasing the hydraulic conductance of the rhizosphere and limiting water flow between roots and soil.

Fig. 2 Hydraulic conductance of the rhizosphere K_{rh} [$\text{m s}^{-1} \text{MPa}^{-1}$] of a sandy and a loamy soil and for three water fluxes at the root-soil interfaces j_r [m s^{-1}]. The large yellow bad is the range of root radial conductance K_r [$\text{m s}^{-1} \text{MPa}^{-1}$], according to Draye et al. (2010). K_{hair} and K_{myc} are the hydraulic conductances of the root hair zone and mycorrhiza estimated using the Hagen-Poiseuille law (Eq. 8).

Water flow in the root

Down to the subcellular scale, primary cell walls are “corridors” for water between protoplasts that contain the cytosol and organelles. Just like in soil, in these fully hydrated corridors whose porosity is about 70%, water flow is driven by gradients in water potential, which is given by the hydrostatic (Ψ_m) (similar to the matric potential defined in soil) and gravitational (Ψ_g) potential. However, pore size in cell walls is extremely small – about $5 \cdot 10^{-9}$ – relative to the dominant porosity class in soils with the finest texture – the clay “ultra-microporosity” spanning the 10^{-7} to $5 \cdot 10^{-6}$ m spectrum. As a consequence, despite large uncertainties, the hydraulic conductivity of cell walls is thought to be orders of magnitude lower than that of heavy clay soils at water saturation. The respective orders of magnitude are: 10^{-10} to 10^{-7} versus 10^{-6} to 10^{-4} m² MPa⁻¹ s⁻¹ as reviewed by [Couvreur et al. \(2018\)](#).

The boundary between the cell wall and the cytosol is the plasma membrane. The inside of this phospholipid bilayer is hydrophobic, which drastically limits the transport of water. However, “gates” to the cytosol exist under the form of transmembrane water channels called aquaporins. Because they decouple the transport of water and solutes, membranes allow the formation of regions with distinct compositions in solutes and different osmolalities. Membranes thereby allow the process of osmosis, which explains how water molecules tend to spontaneously flow toward the side with highest osmolality as a result of their high affinity for solutes. To capture it mathematically, a new component is added to the potential of water: the osmotic potential (Ψ_o , more negative with increasing osmolality). Applying the second law of thermodynamics to water transport, water passively flows down differences of summed Ψ_m , Ψ_g and Ψ_o across selective membranes (the sum of these components is also called total water potential Ψ_{tot}). A membrane failing to decouple water and solute transport is considered as “leaky.” A direct consequence of the leakiness is that the osmotic potential difference across the membrane is not as effective at driving water flow, and Ψ_o is then corrected by a “reflection coefficient” σ equal to zero if the membrane is fully permeable and up to one when fully selective. These principles translate mathematically as follows:

$$j_m = Lp (\Psi_{m,w} - \Psi_{m,c} + \sigma(\Psi_{o,w} - \Psi_{o,c})) \quad (6)$$

where j_m [m s⁻¹] is the water flow rate per unit membrane surface, Lp [m MPa⁻¹ s⁻¹] is the membrane hydraulic conductance per unit surface, $\Psi_{m,w}$ and $\Psi_{m,c}$ [MPa] are the pressure potentials on the sides of the cell wall and cytosol, respectively, and $\Psi_{o,w}$ and $\Psi_{o,c}$ [MPa] the (negative) osmotic potentials on the sides of the cell wall and cytosol, respectively. Note that the gravitational potential is usually neglected at this scale. Lp is defined as conductance per root surface.

The composite nature of the root subcellular structures arranged in parallel and in series allows multiple pathways for water from the root surface to xylem vessels. The apoplastic, transmembrane and symplastic pathways (the last two frequently referred to as the combined cell-to-cell pathway) rely dominantly on water transport through cell walls, plasma membranes and plasmodesmata, respectively. While they have been conceptualized as pathways in parallel with their respective conductivities and reflection coefficients, recent unified modelling and experimental approaches suggest strong alterations of water pathways along the root radius ([Couvreur et al., 2018](#)) and the absence of a purely apoplastic pathway. Hydrophobic root diffusion barriers in the endodermis (and occasionally exodermis) play a key role in both of these observations. The lignin based Casparian strip forms a scaffold in radial cell walls and the suberin lamellae is deposited between all membranes and primary cell walls, drastically limiting permeation across these cell walls and membranes, respectively, in the concerned cell layers. Thereby, these structures locally force water through transmembrane or symplastic pathways, while functionally creating a filter for nutrients responding to the direct environment of roots. There appears to be a high level of coordination between the deposition of diffusion barriers and the expression of specific aquaporins in their direct vicinity so that the relative importance of these multiple factors has been hard to decipher.

The mainstream model for radial water flow across vascular plant roots has remained untouched for multiple decades and is a common building block in Functional-Structural Plant Models. It simply assumes that root tissues are analogous to a “big-membrane,” hence its formulation very close to Eq. (6):

$$j_r = k_r (\Psi_{m,s} - \Psi_{m,x} + \sigma_r(\Psi_{o,s} - \Psi_{o,x})) \quad (7)$$

where j_r [m s⁻¹] is the radial water flux at the root surface, k_r is the root radial conductance per root surface as defined in Eq. (4), σ_r is the root reflection coefficient, $\Psi_{m,s}$ and $\Psi_{m,x}$ [MPa] are the water pressure potentials at root surface and in xylem, respectively, and $\Psi_{o,s}$ and $\Psi_{o,x}$ [MPa] the (negative) osmotic potentials at root surface and in xylem, respectively.

Measured k_r values range between 10^{-9} and 10^{-5} [m s⁻¹ MPa⁻¹] according to [Draye et al. \(2010\)](#) (yellow region in Fig. 2).

Rhizosphere processes and their impact on root water uptake

Root hairs

Root hairs represent about 2% of the root mass but they greatly increase the root surface area, which can be up to 3-fold larger in the presence of root hairs. The volume of soil influenced by roots in the presence of root hairs is further increased by their ability to access finer pores than the main root axis.

Controlled laboratory studies have demonstrated that root hairs facilitate water uptake. [Segal et al. \(2008\)](#) reported a greater depletion of soil water in the root hair zone of the barley (*Hordeum vulgare*) wild type compared with the hairless mutant. Similarly, [Tanaka et al. \(2014\)](#) showed a 47% reduction in water absorption for the hairless mutant of *Arabidopsis thaliana* relative to the wild type. In terms of plant water status, under low evaporative demand in controlled environmental conditions, [Dodd and Diatloff](#)

(2016) showed no difference in the transpiration rate of the no root hairs mutant of barley and the wild-type plants. In contrast, under higher evaporative demands, the ability of root hairs to take up water from drying soil was reported by Carminati et al. (2017b). As soil dried, the leaf water potential of the 'no root hairs' mutant decreased more rapidly than that of the wild type, implying a reduced capacity to take up water at high transpiration rates. Root hairs facilitate water uptake by bridging the gaps between roots and soil, either by directly taking up water or by creating a capillary bridge for water to flow across the gap (Carminati et al., 2017b) and thereby reducing the decline in water potential at the root-soil interface in rapidly transpiring plants.

Field evidence of the significance of root hairs for water uptake by barley under drought was reported by Marin et al. (2021). The field experiment was carried out in Scotland during a typically wet growing season (2017) and during the driest growing season ever recorded at the site (2018), under contrasting soil textures (clay loam and sandy loam). The study showed that root hairs did not confer a notable advantage to barley under optimal conditions, but under soil water deficit, root hairs enhanced plant water status and stress tolerance. This resulted in less negative leaf water potential and lower leaf abscisic acid concentration in the presence of root hairs for plants grown in clay loam, while no significant effect of root hairs was found in sandy loam soil (Marin et al., 2021).

The role of root hairs in plant water uptake has been elucidated mainly in barley. Cai et al. (2021) evaluated the effects of maize root hairs on plant-soil water relations in sand and loam and found no clear effect of root hairs in either soil textures. This might be related to the early shrinkage of root hairs in maize (Duddek et al., 2022). Root hairs show intra- and interspecific variations in length and density. In angiosperms, root hairs vary in length from zero (i.e., species with no root hairs) to 1.5 mm. If comparing barley and maize for instance, barley produces significantly longer root hairs (2-fold) and at a greater root hair length density (6-fold) than maize. Therefore, the role of root hairs in plant water uptake is equivocal, apparently being species and soil specific.

To give an approximate estimation of the capacity of root hairs to transport water, we calculate the effective conductance of root hairs, treating them as capillaries arranged in parallel and using the Hagen-Poiseuille law:

$$j_r = \frac{N \pi r^4 \Delta\psi}{8 \mu L} \quad (8)$$

where j_r is the water flux at the root soil interface [m s^{-1}], N is the number of root hairs per root surface [m^{-3}], r is the hair radius, $\Delta\psi$ is the difference in water potential, μ is viscosity [Pa s] and L is the hair length [m]. K_{hair} is calculated as:

$$K_{\text{hair}} = \frac{N \pi r^4}{8 \mu L} \quad (9)$$

Using $N = 9.5$ (assuming 30 hairs per root length and a root radius of 0.5 mm), hair radius $r = 6 \mu\text{m}$, and setting $L = 10 \text{ mm}$ (to compare it to other domains that were set to 10 mm), we obtain $4.8 \times 10^{-3} \text{ m s}^{-1} \text{ MPa}^{-1}$ (Fig. 2). This is a pretty large value and it might be an overestimate by assuming that viscosity is the same as water and by not adding the permeability of the root membrane. Water has to cross at least one membrane to be taken up by roots. However, it shows how the number of hairs and their radius is potentially sufficient to constitute a significant parallel pathway for water uptake.

Mucilage

Plants contribute a large portion of their photosynthetic products to the soil via their roots in a process called rhizodeposition. Rhizodeposition comprises the release of water-soluble components, the secretion of insoluble components, such as mucilage, the sloughing off of root border cells, the senescence of root epidermis and root hairs, and the release of gases such as CO_2 and ethylene. Mucilage is a polymeric gel that is mainly secreted by the Golgi apparatus of the root cap, but it can also be secreted by the epidermal cells of mature roots (McCully and Boyer, 1997). Its formation is readily visible in air-born roots of maize (Fig. 3). The root tip continuously secretes mucilage in the soil, and as the root elongates, mucilage is translocated along roots. Major components of root mucilage are galactose (~39–42%), fucose (~22–30%), mannose (~11–14%), arabinose (~8–11%), xylose (~1–4%), glucose (~1–4%) and glucuronic acid (~3–5%).

The chemical composition and quantity of mucilage varies across species, developmental stages of plants, and environmental conditions. Despite these variations, mucilage shares common intrinsic properties. Mucilage increases viscosity and lowers the surface tension and water potential of the soil solution. Read and Gregory (1997) showed that the viscosity of maize mucilage is twice that of water already at concentrations of 0.7 mg g^{-1} (weight of dry mucilage per unit weight of the liquid solution), and it increases non-linearly as the concentration of mucilage increases (1000 times higher than pure water at ca. 10 mg g^{-1}). The higher viscosity of mucilage compared to water causes a reduction in the hydraulic conductivity of the rhizosphere. At low concentrations, mucilage increases the saturated hydraulic conductivity of soils with small mean particle size (fine-textured soils), probably due to its swelling capacity and the consequent increase in soil porosity. However, as mucilage concentration increases, the saturated hydraulic conductivity decreases dramatically. Mucilage has a smaller surface tension than pure water, probably due to the presence of phospholipid components in the root exudates. Read and Gregory (1997) found that the surface tension rapidly declined with increasing mucilage concentration, decreasing from $72 \text{ [mN m}^{-1}]$ down to $45\text{--}50 \text{ mN m}^{-1}$ at concentrations of 1 mg g^{-1} in water. McCully and Boyer (1997) found that when fully saturated mucilage exuded by the nodal roots of the maize plant can hold an amount of water 300 times its dry weight, but a large fraction of this water could not be held against negative water potentials as the soil dries. These authors concluded that mucilage should not play a significant role in soil-plant water relations. However, when mucilage is embedded into a solid matrix, it increases the water holding capacity of the soil at any given water potential (Carminati

Fig. 3 Mucilage secreted by nodal roots of the maize plant. The photo was taken a day after a rain event in the field.

et al., 2017a). This evidence suggests that the effect of mucilage on soil water retention must be amplified in soils by additional forces that emerge from the interaction between polymers and soil matrix.

Mucilage of most plants contains a small fraction of phospholipids and anionic polysaccharides. These components are amphiphilic substances that contain both hydrophilic and hydrophobic functional regions. Therefore, when mucilage dries, the hydrophilic regions of these components may bind to each other or to the soil and expose the hydrophobic parts toward the air-filled phase of the pore space, causing water repellency in the rhizosphere (Hallett et al., 2003).

Several hypothetical functions have been attributed to mucilage such as impacting the dynamics of nutrients in the rhizosphere, keeping the soil surrounding the root tip wet and hydrated (McCully and Boyer, 1997) and therefore protecting root tips from dehydration in drying soil, acting as a lubricant at the root surface, thereby improving root penetration in soil, and improving the contact between roots and soil particles. Another putative function attributed to mucilage is the facilitation of water and nutrient uptake by roots. This beneficial function is related to an improved contact between roots and the soil, improving the soil's water-holding capacity, and improved connectivity of the liquid phase within soil pores by altering the liquid configuration. Carminati et al. (2017a) conceptualized the function of mucilage in the retention and flow of water in drying soil. They showed that the combination of increased viscosity and decreased surface tension of the liquid phase could alter the spatial configuration of the liquid phase within the soil pores, enhancing the connectivity of the liquid phase during soil drying.

Mycorrhizal fungi

The vast majority of land plants form associations with mycorrhizal fungi. Four main types of mycorrhizas are recognized based on morphological characteristics of root tissues and host plants: arbuscular mycorrhizas, ectomycorrhizas, ericoid mycorrhizas and orchid mycorrhizas, that form associations with 72%, 2%, 1.5% and 10% of vascular plants, respectively. Arbuscular mycorrhizal fungi (AMF) are therefore, by far, the more widespread, distributed in the majority of terrestrial ecosystems and which concern the vast majority of agricultural and horticultural crops. We will thus focus our attention on this main guild of mycorrhizal fungi.

Arbuscular mycorrhizal fungi are obligate root symbionts that have co-evolved with land plants for more than 400 million years. Their roles in plant nutrition and growth as well as alleviation of biotic and abiotic stresses have been repeatedly demonstrated, making these soil microorganisms key players in crop production (Smith and Read, 2008) and plant ecology in natural systems. AMF colonize the cortical cells of the root system, developing intraradical mycelium (IRM) and arbuscules, and extend tens of cm away from the roots into the soil as extraradical mycelium (ERM), colonizing soil pores with hyphae having diameters up to 10 times finer than that of root hairs. They produce up to 100 m of hyphae per gram of soil in pastures and prairies (Miller et al., 1995). ERM can thus be considered as an extension of the root system, increasing the uptake of minerals (e.g., phosphorus, nitrogen) and water, meeting plant nutritional needs, in exchange for organic compounds issued from the photosynthesis.

The role of AMF in the water supply of plants has been reported since the early 1970s. Safir et al. (1971) were the first to suggest that the symbiosis of AMF with soybean affects the water relations, probably via improved phosphorus (P) nutrition. This

hypothesis was supported up to the 1980s until a couple of studies demonstrated that AMF could also affect water relations by other mechanisms than P nutrition (Harris et al., 1985). Since then, several hypotheses have been proposed and are still being explored.

Fungal ERM allow AMF-colonized plants to explore more soil, accessing pores unreachable to roots and root hairs, taking up more water than non-colonized plants and transporting water via the hyphae from far distances to the roots. The tridimensional ERM structures maintain water continuity from soils to plant by by-passing air gaps. The hyphal length per unit soil mass (m g^{-1}) reported in the field varies from 68 to 101 in prairie (Miller et al., 1995), 45 to 74 in ungrazed pasture (Miller et al., 1995) and 10 to 35 in maize cropping (Kabir and Koide, 2002). The diameter of hyphae in the soil generally varies from 1.2 to 18 μm with the smallest ones involved in uptake being approximately 2 μm . Their growth is estimated between 0.3 and 3.3 mm a day with values reported for *Rhizophagus fasciculatum* symbiotic with *Trifolium subterraneum* of 10 m g^{-1} after four weeks and 20 m g^{-1} after 5 weeks (Scheltema et al., 1985).

AMF strongly affects the expression of aquaporins (i.e., water channels) involved in the transport of water. Aquaporins have been reported in the hyphae developing within the soil (favoring the entry of water within the hyphae) as well as in the peri-arbuscular membrane, which is the membrane that surrounds an arbuscule and is contiguous to the plasma membrane of the cortical cell (it plays a central role in nutrient exchange between the symbionts). Kikuchi et al. (2016) proposed a model in which plant transpiration creates a water potential gradient, allowing water to move within the extraradical hyphae through the cytosol toward the cortical cells. A mycorrhiza-inducible plant aquaporin on the periarbuscular membrane and an aquaglyceroporin located on the fungal plasma membrane (responsible for water transport across the plasma membrane) further mediate the water flow from fungal cell to root cell. Thus, root colonization impacts gene expression of aquaporins, which is correlated with changes in root hydraulic properties that increase water transport capacity of mycorrhizal roots. In the model proposed by Kikuchi et al. (2016), water may also move through the lumen of tubular vacuoles containing aquaporins. Interestingly, inorganic phosphorus accumulates within these tubular vacuoles and is translocated toward the roots by the water flow. Host transpiration and the fungal aquaporin thus play key roles in P translocation.

Stimulation of root hair growth and protection of host plants against the oxidative damage under abiotic, including osmotic stresses, have also been reported. Gas exchange capacities were also increased in AMF-colonized plants, probably associated with a decrease in stomatal resistance and increase in transpiration as reported by Zhu et al. (2011) in maize. Finally, AMF have been shown to impact plant water uptake capacity indirectly by the production of exudates, which alter soil pore structure through aggregation and can also influence hydrophobicity.

We repeated the calculations described above for root hairs but using $r = 1 \mu\text{m}$, $L = 1 \text{ cm}$ and $N = 100$ (estimated assuming 20 m of ERM per gram of soil, a root length density of 2 cm cm^{-3}) appropriate for AMF hyphae. Using Eq. (8), we obtain $K_{\text{myc}} = 3.9 \cdot 10^{-6} [\text{m s}^{-1} \text{ MPa}^{-1}]$ (Fig. 2). This value is much smaller than that calculated for root hairs, due to the smaller radius of ERM hyphae, however it is larger than the conductance of a sandy soil for soil matric potentials more negative than -200 hPa to -500 hPa , while it needs 10 times more negative water potential in a loam for mycorrhiza to be as conductive as the soil matrix. This simple calculation suggests that a significant flow across mycorrhizae can take place, particularly in coarse textured soils.

Rhizosphere hydraulic properties

Plant water uptake from the soil is influenced by the hydraulic properties of the rhizosphere, which differ from those of bulk soil as a result of biophysical processes occurring at the root-soil interface as discussed above. Processes affecting rhizosphere hydraulic properties include soil compaction by root growth, air-filled gaps caused by roots and soil shrinking and swelling during drying and wetting cycles, root hair intrusion, and mucilage production. Imaging methods have provided insight into the dynamics of water content and soil structure around the roots. X-ray CT has been particularly useful for resolving the soil structure dynamics around the roots. Aravena et al. (2011) showed that root-induced compaction increases contact areas between aggregates, leading to an increase in unsaturated hydraulic conductivity of the rhizosphere soil. Koebemick et al. (2017) investigated the effect of root hairs on soil porosity and pore connectivity, reporting increased soil macroporosity in the rhizosphere in the presence of root hairs. As roots shrink, they create gaps between soil and roots, reducing water transfers and therefore helping plants to prevent water loss when the soil dries.

Neutron radiography and tomography have been useful to reveal unexpected gradients in water content around the roots, with increasing water contents toward the root surface during the drying phase (Carminati et al., 2010). These contradictory observations were explained as the effect of mucilage exuded by roots on water holding capacity and rhizosphere hydrophobicity of the rhizosphere. Hallett et al. (2003) directly measured the hydraulic characteristics of the rhizosphere using a miniaturized infiltrometer device and found reduced water sorptivity in moist rhizosphere soil of barley compared with bulk soil, due to increased water repellency in the rhizosphere.

The increased hydrophobicity induced by mucilage in the rhizosphere also results in a high contact angle between liquid phase and soil particles (Moradi et al., 2012). Zarebanadkouki et al. (2016) found that during a drying and wetting cycle in a sandy soil, the hydraulic conductivity of the root-soil interface creates a temporary limit to root water uptake as a result of rhizosphere hydrophobicity. They showed that water repellency of the rhizosphere reduced root water uptake by a factor of 6.5 times during the first 2–3 h after irrigation. Despite the occurrence and mechanisms of water repellency in the rhizosphere being partly clarified, their consequences on emerging water relations between soil and plants remain unclear. The reason is that rhizosphere hydrophobicity is often observed as a local phenomenon along the root system and it is not clear if this local limitation of root water uptake has any

impact on the overall soil-plant water relationship. Rhizosphere hydrophobicity might even be a positive rhizosphere trait that hydraulically disconnects the root segments from the driest soil layers, therefore reducing leakage of water from root system to the dry soil. Rhizosphere hydrophobicity could locally and temporarily disconnect the root segment located in the driest soil layers, therefore reducing the risk of hydraulic failure.

Rhizosphere hydraulic properties also differ from those of bulk soil also as a result of other biofilms present in the soil, such as extracellular polymeric substances (EPS) secreted by bacteria and exudates from mycorrhizal fungi. Similar to mucilage, these materials connecting soil particles do not break up upon drying, due to their high viscosity and low surface tension, enhancing the soil water retention and connectivity of the liquid phase.

Root water uptake and rhizosphere properties in their ecological and environmental context

The physics of soil water flow indicates that soil drying and the consequent drop in soil hydraulic conductivity limit the availability of water to plants. The drop in soil hydraulic conductivity around the roots is exacerbated by soil and root shrinkage and the consequent reduction in root-soil contact, which causes a further loss of conductivity.

Plants can respond to such limitations in soil water availability with multiple strategies. One strategy is to reduce the transpiration demand by closing stomata, with the cost of reduced growth and carbon assimilation. A second strategy is to increase the surface of roots active in water uptake. A combination of both strategies is the allocation of more carbon to roots compared to shoot, which reduces the ratio between transpiration and root surface active in water uptake. An additional strategy is the modification of rhizosphere properties.

The three previous sections reviewed the several mechanisms that plants have to engineer the physical properties of their rhizosphere. Growth of root hairs and symbiosis with mycorrhiza increase the capacity of roots to extract water from dry and low conductive soils and thus increase the plant water potential needed to sustain transpiration during drought. However, their effectiveness is soil and plant specific. The additional strategy for plant roots is to modify their rhizosphere by the secretion of mucilage. Mucilage secretion leads to a wetter and more hydraulically connected rhizosphere compared to the bulk soil during drying, and to a less severe decrease in unsaturated hydraulic conductivity and diffusion coefficient. On the other hand, mucilage induces a temporary water repellency in the rhizosphere, particularly in sandy soils, which might be functional to maintain the region around the roots aerated upon rewetting and regulate water efflux from roots to dry soils layers. Despite its potential to maintain the connectivity between soil and roots, the relevance of mucilage on root water uptake has not yet been demonstrated due to challenges in quantifying the amount and properties of mucilage in-situ and to the lack of appropriate mucilage deficient genotypes. EPS produced by microorganisms have similar properties as mucilage and, one can speculate, have a similar beneficial role on root water uptake, indicating the important link between plants and soil microbiota for soil water resources.

Root strategies to improve the acquisition of water from the soil can be summarized in two groups: (1) root development and exploration of larger volumes of soil; and (2) improvement of the hydraulic conductivity of the rhizosphere via root hairs, mycorrhiza and the production of biofilms. Both strategies require a carbon input: the first strategy requires carbon input for plant growth; the second strategy consists in the investment of carbon into the rhizosphere. The two strategies are not alternatives and are likely to be coordinated in space and time. Hairs and mucilage are functional for some time, then hairs shrink (Duddek et al., 2022) and mucilage is degraded. Therefore, their production must match with the root development in such a way that these traits are active in the root segments that are hydraulically active (radially and axially).

In summary, we have shown the physics of soil water flow to the root and how, during soil drying, the local drop in conductivity around the roots becomes a limiting factor for transpiration. Plants have multiple mechanisms to cope with soil hydraulic limitation. Prominent examples are root hairs, mycorrhiza and mucilage exudation. Understanding plant and soil interactions in the rhizosphere is a key challenge in soil and plant research and it has important implications for the ability of plants to cope with drought. Finally, it should be noted that to fully comprehend the implications of rhizosphere processes, one should include these processes into a root system perspective, where roots dynamically grow in a variable (in space and time) soil.

Abstract

Water flows in the soil-plant-atmosphere system from higher to lower water potentials. The rate that water flows depends on potential differences and conductances along the different parts of the water flow pathways from soil to root, shoot, leaves, and atmosphere. Soil-plant-atmosphere models simulate water uptake from the soil by plant roots based on this principle, but differ in their representation of flow paths in the system which ranges from detailed representations of the 3D root architecture to a single flow path from a lumped root zone. By upscaling, detailed information about soil and root properties can be implemented in lumped models.

Key points

- Models of root water uptake, depending on both plant and soil properties are reviewed.
- With root age, root hydraulics change, with young tips taking up water at the most rapid rate.
- Roots redistribute water based on water potential gradients in the soil and plant tissue.
- Understanding root water uptake in detail aids the selection of ideotypes in crop breeding.

Introduction

Evaporation from the land surface is an important component of the terrestrial water cycle and on a global scale, it equates to about 60–70% of the total amount of continental precipitation. There are two main fluxes of evaporation: a flux of water that evaporates from the surface of mesophyll cells within plant leaves and exits the plant through the stomata (little openings in the leaf), often called the transpiration flux (T), and a flux of water that evaporates from surfaces (E), such as the soil surface, leaf surfaces that have intercepted rainwater, and open water surfaces of rivers and lakes. The sum of both fluxes is evapotranspiration (ET). Since the evaporation of water consumes considerable energy, evapotranspiration is a key component of the land surface energy balance. When the amount of water that is transported away from the surface can be supplied by new water that flows to the evaporating surfaces (e.g., the internal cavities below the open stomata, or the soil surface) the air at the evaporating surface remains saturated with water and the evapotranspiration rate can be derived from solving a surface energy balance that is coupled with a description of vapor and sensible heat transfers in the atmospheric boundary layer. Under these conditions, evapotranspiration is ‘energy limited’ and occurs at a ‘potential’ rate. This potential evapotranspiration, ET_{pot} , corresponds to the evaporation from a ‘well-watered’ surface and it ranges from 1 mm d⁻¹ for cool and humid weather conditions up to 10 mm d⁻¹ for hot and dry conditions (1 mm of water evaporated corresponds to 1 L of water that evaporates from a 1 m² surface). A simple approach to splitting up the potential evapotranspiration of a crop, ET_{pot} , into evaporation from the soil surface, E_{pot} , and transpiration, T_{pot} , uses Beer’s Law and splits up total energy that is absorbed by the surface into a part that is absorbed by the canopy and is used for transpiration, and a part that is used for soil water evaporation (Ritchie, 1972):

$$T_{pot} = ET_{pot}(1 - \exp(-\kappa LAI)) \quad (1)$$

where LAI is the leaf area index or the surface area of the leaves that covers a unit of soil surface [$\text{m}^2 \text{m}^{-2}$], and κ $[-]$ is an extinction coefficient that ranges between 0.4 and 0.75 for different crops and vegetation types.

The supply of water for evapotranspiration is provided by water flowing through the soil-plant system towards the evaporation surfaces. The water stored in vegetation ranges roughly from 5 to 10 kg m^{-2} for crops and grassland, to 30–40 kg m^{-2} for forests (roughly calculated from dry matter estimates (Whittaker and Likens, 1973) and a plant moisture content of 500–1000% (kg of water kg^{-1} dry weight) for crops and grasses and 100% for living wood) which is not much larger than the typical daily transpiration of 5 kg m^{-2} . In consequence, the transpiration rate is almost instantaneously translated into water uptake from the soil by roots. Water stored in trees can be depleted and used for transpiration, which leads to a phase shift between diurnal transpiration and root water uptake cycles. The water stored in trees, however, is insufficient to supply the transpiration demand over several days. When the water supply is insufficient to supply the evapotranspiration demand, the evapotranspiration becomes supply limited and is reduced compared with ET_{pot} . Since the extraction of water from the soil profile by evaporation and transpiration occurs over different ranges of depths, the dynamics of these processes in response to a drought spell differ considerably. Evaporation from the soil surface can dry out only a few cm of the soil profile, 0.1–0.15 m according to Allen et al. (1998), so that the evaporation becomes supply-limited relatively rapidly. Boesten and Stroosnijder (1986) found that in temperate humid climates, evaporation can become supply limited in as little as 2 days after the last rainfall. Plants can extract water over the extent of their whole root system and dry out the soil much deeper than evaporation from the soil surface. Maximal root depths vary strongly depending on the vegetation type, climate, soil texture, and groundwater table depth. A compilation by Fan et al. (2017) of maximal rooting depths reported in several studies showed a large variation ranging from 1 m to tens of meters, with a maximal observed root depth of 68 m of Shepherd's tree (*Boscia albitrunca*) in the Kalahari desert. Teuling et al. (2006) observed an e-folding decay rate of several weeks for transpiration (i.e., the period over which the transpiration shrinks by 63%) by deep rooted vegetation. This illustrates that plants may tap a large stock of deep soil water that helps them keep up transpiration during long dry spells.

Roots are not uniformly distributed in soil profiles and root densities decline strongly with depth. On average, 50% of the root mass is found in the upper 0.3 m of the soil profile whereas 95% of the root mass can be found in the upper 2 m (Schenk and Jackson, 2002), but there are large variations between vegetation, climate, and soil. Estimating how much water can be extracted by the root system depends on how water and roots are distributed in the soil profile.

In this chapter, we link the detailed description of water uptake by single root segments and how it is influenced by the soil properties in the rhizosphere, the small soil volume surrounded and influenced by roots, to the description of the plant available water in the entire root zone. We describe which soil and root properties define the relation between soil water content and its distribution in the soil profile and plant water uptake. This relationship is important to predict the impact on vegetation stress, growth, and carbon assimilation of prolonged drought spells, which are forecast by climate models for several regions of the world. It also plays a crucial role in irrigation scheduling to control the crop's root zone soil moisture.

Mechanisms and characteristics of water flow in the soil-plant system

Water is absorbed in the liquid state by the roots from the soil. The general flow pattern is shown in Fig. 1: soil $\rightarrow$ root cells $\rightarrow$ endodermis $\rightarrow$ xylem $\rightarrow$ leaf cells $\rightarrow$ stomata $\rightarrow$ air (the latter as vapor flow). Most of the transport ($>80\%$) through the root and leaf cells takes place along the microcapillaries situated in the cell wall. However, the roots contain endodermis cells in which the continuous system of microcapillaries in the cell walls is interrupted by the so-called Casparian strips. Consequently, most of the water moving through a plant has to pass through the cells itself. This means that the permeability of the endodermis cell and the

Fig. 1 Water flow path in the soil-plant-atmosphere continuum (SPAC) and water potentials and conductances in different parts of the continuum.

semipermeable membrane (plasmalemma) can be an important determinant in controlling the water flow. Hence cold soil temperature or poor soil aeration will induce a low level of metabolic activity in the endodermis cells, which may cause a large resistance across the semipermeable membrane against water uptake.

Water in this system flows from locations with a high total water potential to locations with a lower potential (generally expressed as negative values, being under suction). The total water potential is defined as the energy required to bring a unit amount of water from a reference state, normally defined as free, pure liquid water at atmospheric pressure and at a reference height, to a certain state. In soil hydrology, the unit amount of water is defined in terms of a mass of water multiplied by the gravitational acceleration, with the units of the water potential corresponding with length units. The total water potential expressed in length units, h_T , represents the energy required to move water along an equivalent water column with height h_T . In plant sciences, the unit amount of water is defined as a unit volume of water and the units of the total water potential are pressure units, ψ_T . h_T and ψ_T are related as:

$$h_T = \frac{\psi_T}{\rho_w g} \quad (2)$$

where ρ_w is the mass density of water and g the gravitational acceleration rate. For $g \approx 10 \text{ m s}^{-2}$, $h_T [\text{m}] \approx 10^2 \psi_T [\text{MPa}]$. We will use length units to express total water potentials. Total water potentials can be split into partial potentials and for soil-plant systems, the following partial potentials are of relevance:

$$h_T = h_g(z) + h_o(c) + h_p \quad (3)$$

where $h_g(z)$ is the gravitational potential, $h_o(c)$, the osmotic potential, and h_p the pressure potential. $h_g(z)$ represents the energy that is required to move water against the gravitational force and simply corresponds with the elevation, z , above the reference level. $h_o(c)$ is the osmotic potential and represents the energy that is required to move pure water into a solution across a membrane that is permeable for water molecules but not for ions (e.g., plant cell membranes). The osmotic potential h_o is related to the salt concentration in the soil pores or in the plant cells, c , and is negative since energy is released when pure water is mixed with a solution:

$$h_o = - \frac{RT \sum_i c_i}{\rho_w g} \quad (4)$$

where R is the universal gas constant ($8.314 \text{ J K}^{-1} \text{ mol}^{-1}$), T the absolute temperature [K], c_i the concentration of ion i in the soil solution [mol m^{-3}]. h_p is the pressure potential and corresponds with the difference in the water pressure and the reference water pressure, i.e., the atmospheric pressure. h_p in unsaturated soils is typically negative, i.e., lower than the atmospheric pressure, since attractive forces of pore walls generate curved air-water interfaces across which a pressure drop results from the air-water surface tension, and it decreases with decreasing soil moisture content. In living plant cells that are not supported by strong cell walls, e.g., leaf cells, h_p must be positive to maintain cell turgor. This implies that osmotic potential in these cells must be negative to sustain water flow from the soil to the leaves, or to avoid leaves losing water to the soil. At very negative total water potentials, the osmotic potential cannot be kept sufficiently low, so that the turgor of the cells is lost and plants wilt. To avoid leaf water potentials dropping to too low values when the soil dries out or when the transpiration stream is large, plants reduce transpiration by stomatal closure which results from turgor loss in stomatal guard cells. During the night, when transpiration is close to zero, the plant water potentials equilibrate again with the soil water potentials and plants regain turgor. Examples of potentials and partial potentials in different parts of the soil-plant system during daytime when plants transpire are given in Table 1. In xylem vessels, which are made up of dead cells without cell membranes, very negative water pressure potentials far below -10 m may occur so that water is under tension and in a metastable state. The strong molecular cohesion forces of water in combination with the anatomical properties of the xylem can sustain this metastable state of water. Strong cell walls and small holes or pits in the order of tens of nanometers connecting vessels, avoid the collapse of xylem vessels and avoid the formation of air bubbles or embolisms that can spread through the vessels and block the water flow. The cohesion-tension theory, introduced already at the end of the 19th century (Böhm, 1893; Dixon and Joly, 1895), states that water is pulled by negative pressures in the plant from the soil into the plant. The existence of such low and negative pressures or tensions of water in the xylem is debated

Table 1 Illustration of total water potentials (h_T) and partial potentials (all in m) in a tree-soil system: gravitational potential (h_g ; reference level is the soil surface), osmotic potentials (h_o), and pressure potentials (h_p) in the soil, root xylem, stem xylem, and leaves for wet and dry soil conditions.

Compartment	Wet soil				Dry soil			
	h_T	h_g	h_o	h_p	h_T	h_g	h_o	h_p
Soil	-1.5	-0.5	0	-1	-150	-0.5	0	-149.5
Root xylem	-30.5	-0.5	-10	-20	-170	-0.5	-10	-159.5
Stem xylem	-70	10	-10	-70	-250	10	-10	-250
Leaves	-100	10	-160	50	-300	10	-310	0

Partially after Rodríguez-Iturbe and Porporato (2004).

and other mechanisms that lead to low water potentials, e.g., attractive forces to cell walls and network structures of gels generating a matric potential, have been proposed.

For water fluxes in the soil plant system, the total water potentials are of importance and in general, the following relation between T and the total water potentials in the bulk soil of the root zone, $h_{T,soil}$ and in the plant, $h_{T,plant}$ can be defined:

$$T = K_{rs} (h_{T,soil} - h_{T,plant}) \quad (5)$$

where K_{rs} is the soil-plant conductance that represents the lumped conductance of the flow path from the soil to the leaves. Its units depend on whether the transpiration is determined as the volume of water taken up per plant and per time [$\text{m}^3 \text{d}^{-1}$] or as the volume of water taken up by the vegetation per unit of soil surface area per time [d^{-1}]. Based on observations that even in wet soils (i.e., $h_{T,soil} \approx 0$) crops may wilt during midday (i.e., $h_{T,leaf} \approx -150 \text{ m}$) on days when the transpiration rate is large (for daily averaged transpiration rate between 8 and 9 mm d^{-1} , the transpiration rate at midday is around 30 mm d^{-1}), a rough estimate of the plant part of K_{rs} yields $K_{rs} = 2 \times 10^{-4} \text{ d}^{-1}$ (Cowan, 1965). Of course, this value depends strongly on the crop or vegetation type and only gives an order of magnitude. Simplifying this flow path to a single path that crosses different compartments, as illustrated in Fig. 1, K_{rs} may be split up using Ohm's Law in partial conductances as:

$$K_{rs} = \left(K_{soil-root}^{-1} + K_{cortex}^{-1} + K_{endodermis}^{-1} + K_{xylem}^{-1} + K_{leafcells}^{-1} \right)^{-1} \quad (6)$$

These conductances are extensive properties and their values include the length of the flow path through the compartment and the cross-sectional area of the flow path. Multiplying these conductances by the path length and dividing them by the cross-sectional area, conductivities, which are intrinsic properties, are obtained. The xylem conductivity is in general eight orders of magnitude larger than the root radial conductivity (lumped cortex and endodermis conductivity). But, as the xylem constitutes all but 1 mm of the total flow path length in the plant, that means 99.9% of the flow path length in a 1 m high maize plant and 99.99% of the flow path length in a 10 m high tree. Considering that the cross-sectional area of flow through the xylem is much smaller than the absorbance surface of roots, the xylem conductance and non-xylem conductance (lumped cortex, endodermis, and leaf cell conductances) are of similar magnitude in plants (Sperry et al., 2003). The soil and xylem conductances decrease when the water pressures become more negative. The pressure potential at which the xylem conductivity drops to 50% of the fully saturated conductivity is generally lower than -100 m and lower than the pressure potential at which stomata start closing (Carminati and Javaux, 2020). This suggests that plants try to avoid failure of the xylem by closing stomata and controlling the plant water potential. It also implies that the plant conductance may be considered to be independent of the plant water potential when the plant is not extremely stressed.

For wet soil conditions, the hydraulic conductivity of the soil is considerably higher than that of root tissues and potential drops along the soil-root-leaf pathways occur mainly within the plant (Fig. 2) (Draye et al., 2010). For drier soil conditions, i.e., for

Fig. 2 Envelopes of typical soil conductivity curves (purple area) and apparent root conductivity values assuming an averaged radius of 250 μm (green area) redrawn from the literature. The upper right plot represents root conductivity values from 19 studies. Adapted from Draye X, Kim Y, Lobet G and Javaux M (2010) Model-assisted integration of physiological and environmental constraints affecting the dynamic and spatial patterns of root water uptake from soils. *Journal of Experimental Botany* 61: 2145–2155, where the original reference sources can be found.

pressure potentials smaller than -1 m in sand and -10 m in loam down to -150 m in clay, the conductivity of the soil becomes limiting and large pressure drops between the bulk soil and the soil-root interface emerge and Eq. (5) becomes nonlinear. Since the water capacity of the soil, i.e., how the soil water content changes per unit change of soil water pressure, is very low when the soil-root conductance becomes limiting, soil and plant water potentials drop rapidly when the soil dries out further. To avoid a drop in plant water potentials that disrupts the flow path in the xylem within the reaction time of stomata, stomata should close and reduce the transpiration losses at plant water potentials that are far above damaging pressures in the xylem. The critical leaf water potentials at which stomata start closing should therefore be far above the damaging pressures in the xylem and should adapt to the soil properties and the transpiration rates (Carminati and Javaux, 2020). The mechanism that closes stomata is turgor loss of the guard cells when water potentials in these cells become too low. Since guard cells are hydraulically connected to the other cells in the leaf, the leaf water potential is the direct signal for stomatal closure. However, many different signals play a role in stomatal regulation, which affect the dynamics and the magnitude of the stomatal response to a decrease in water potential (Lawson and Matthews, 2020). An additional signal that measures the change in transpiration rate per unit change in leaf water potential and to which stomata respond has been proposed (Carminati and Javaux, 2020). This would allow plants to sense non-linearities in the soil-plant flow path and control transpiration and plant pressure losses by timely closing of stomata. Stomatal regulation strategy is sometimes split between isohydric and anisohydric behavior. While plants with isohydric behavior have a strict stomatal regulation to keep leaf water potentials above a limiting threshold, plants with anisohydric behavior have a smoother stomatal regulation that generates greater variation of leaf water potentials with transpiration rate. The simplest way to represent the effect of drought on transpiration and root water uptake for an isohydric plant is to assume that when a critical leaf water potential is reached, stomata (partially) close and reduce the transpiration rate so that the leaf water potentials do not drop below this critical leaf water potential. The critical leaf water potentials that plants try to keep constant by reducing the transpiration depend on the plant species, but as discussed above, may also depend on the soil type and transpiration demand.

Eqs. (5) and (6) are useful to obtain a qualitative overview of the flow process in the soil-plant system and the water potential and of pressure drops along the flow path in this system. However, for a quantitative prediction, more detailed descriptions are required. The main reason is the spatial variation of soil water potentials, soil moisture contents, and root distributions in the root zone. The largest variations are with depth, but lateral variations may also be significant. The interplay between non-uniform water potentials and non-uniform root distributions in the root zone in combination with non-linear conductances in the system (i.e., conductances that depend on water potentials), needs to be understood to determine an average soil water potential in the root zone and the soil-plant conductance. This is needed to calculate the plant water potential and transpiration. How these root zone averaged potentials, conductances, and water fluxes change with time depends on the distribution of the water uptake from the soil profile and how water redistribution in the soil-plant system can compensate for spatial variations in root water uptake. Vertical and lateral variations in soil water potential result in, but are also caused by, non-uniform water uptake due to non-uniform root distributions in the root zone. Starting from a uniformly wet soil profile or a soil profile with a uniform soil water potential, water uptake occurs mainly in the upper soil layers where the root density is largest (largest absorbing root surface) and from where the flow path distance through the xylem to the transpiring leaf surfaces is the smallest. This results in faster drying by roots of the upper than the deeper soil layers and a stronger decrease in soil water potentials in the upper than in the deeper layers. To maintain the transpiration rate, the plant water potential will decrease and the difference between soil and plant water potential will become larger in the deeper soil layers than in the upper layer. As a consequence, the uptake from the drier upper soil layers will decrease and be compensated by increased uptake from deeper layers. Fig. 3 shows an example of this phenomenon that was observed in a lysimeter during the growing season of a spring barley crop. With time, the upper soil layers dry out and the root system progressively starts depleting deeper soil layers. This “moving sink” phenomenon is called root water uptake compensation.

During the night, when transpiration from leaves is close to zero, the water potential in the plant tends to equilibrate with the average soil water potential. The difference in water potential between the upper and the deeper soil then induces a water flow from the deeper soil layers to the upper soil via the root system that bypasses the water flow through the soil pores. This phenomenon of water uptake by deeper roots and root exudation in shallower layers is called hydraulic lift. Roots of deep rooting trees provide direct connections and transfer water over tens of meters between deeper soil layers, where they may tap from groundwater, and surface soil layers. The magnitude of these water transfers ranges from 0.04 to 1.3 mm d^{-1} in the empirical literature, and from 0.1 to 3.23 mm d^{-1} in the modeling literature (Neumann and Cardon, 2012). Hydraulic lift continues the uptake process during the night and provides a water stock that is easily accessible during the day. It may also support shallow rooting vegetation with water and keep the upper soil layers moist so that microbial activity, which mineralizes organic material and releases nutrients for plants; and nutrient mobility in the upper layers are maintained. The redistribution of water in the soil profile via roots may also occur in the downward direction when the upper soil layers are rewetted by precipitation and the lower soil layers are dry. This downward transfer via roots avoids water loss by evaporation from the soil surface so it can be used later by the vegetation. Hydraulic redistribution via the root system and root water uptake compensation play an important role in the water supply of seasonally dry ecosystems (Amenu and Kumar, 2008) (Fig. 4). The impact of hydraulic lift and root redistribution on water uptake depends on the interplay between the root distribution, the root, and soil hydraulic properties. Using a simulation study with root systems that have a high or a low root radial conductivity and an infinite xylem conductivity, which lead to, respectively a large and small hydraulic redistribution via the root system, it was found that hydraulic redistribution had the largest impact in root systems with a non-uniform root distribution. The effect of different root conductivities and hydraulic redistribution on the water uptake was found to be similar in different soil types.

Description of uptake using models

Uptake based on root hydraulics (non-saline soils)

The single flow path in the soil-root-plant system shown in Fig. 1 can be split up in several flow paths from the soil to the absorbing surfaces of single root segments and within the connected root segments to the root collar and further to the leaves. When neglecting the water storage in root segments, the root system can be represented by a network of leaky pipes and the flow in a single root segment is described by:

$$\frac{d}{d\ell} k_x \frac{dh_{T,xylem}}{d\ell} = -2\pi r_{root} k_r (h_{T,soil-root} - h_{T,xylem}) \quad (7)$$

where ℓ is the axial coordinate of the root, k_x [$\text{m}^3 \text{s}^{-1}$] and k_r [s^{-1}] are the intrinsic axial and radial root segment conductances, r_{root} is the root segment radius, and $h_{T,xylem}$ [m] and $h_{T,soil-root}$ [m] are the water potentials in, respectively, the xylem and at the soil-root interface, which include both the pressure potential and the elevation potential (osmotic potentials are not included here). k_r lumps the cortex and endodermis conductances. Where two, or more segments come together in a root branch, the xylem pressures at the connection point are the same for all segments and the flow towards that connection point equals the flow away from it. When $h_{T,soil-root}$ is known along all root segments, the uptake along each root segment and the distribution of $h_{T,xylem}$ in the entire root system can be calculated. The intrinsic conductances depend on the plant species, but large variations of these properties may also be observed between different plant genotypes of the same species. Furthermore, they can also be ‘plastic’ root properties that adapt to the soil and climate conditions. k_r and k_x vary over time or with distance along a root from its distal (youngest) to its proximal (oldest) ends. With the maturation of the xylem, k_x increases to a maximal value whereas the development of Casparian strips leads to a reduction of k_r with root age (Fig. 5a and b).

Considering a single root with constant k_x and k_r , the uptake along the root decreases with distance from the proximal end of the root since the pressure in the xylem increases. An analytical solution can be derived that expresses the uptake and the xylem pressures along the root as a function of the following dimensionless parameter α (Landsberg and Fowkes, 1978):

$$\alpha = l_{root} \sqrt{\frac{2\pi r k_r}{k_x}} \quad (8)$$

For larger α values, the uptake declines more from the proximal to the distal end of the root, whereas it is more homogeneous for small α values. The ratio of radial to axial root conductance and α therefore define a maximal root length along which water can be taken up effectively from a soil profile with a homogeneous soil water potential. Considering ranges of observed conductances, these analytical solutions indicate that root water uptake by a root segment depends on the distance of the segment to the root collar and that xylem conductances can be limiting for root water absorbance. The water uptake along a single root is also strongly affected by the distribution of conductances along the root. The lower k_r near the proximal (older) and higher k_r near the distal end of the root and the opposite for k_x lead to more uptake near the root tips. This is shown for a lateral root of maize in Fig. 5. A growing root with a non-uniform distribution of k_r and k_x leading to a higher uptake near root tips can better explore and access water deeper in the soil profile than a root with constant k_x and k_r values, which will focus uptake near the proximal end.

For real root architectures and for non-homogenous soil water potential distributions, the flow into and within the root network can be calculated numerically when the soil water potentials at the soil root interfaces, $h_{T,soil-root}$ are known (Fig. 6). To simulate soil

Fig. 5 Distribution along the length of a lateral maize root, z (with $z = 0$ at the root tip), of: radial root conductivity k_r (a), axial root conductivity k_x (b), and ‘standard uptake density’ (SUD, fraction of uptake per unit root length for a uniform soil water potential). Blue lines represent a root with a non-uniform distribution of k_r and k_x and red lines represent roots with uniform k_x and k_r . 1 hPa is equivalent to a pressure head of approximately 1 cm. Fig. 6 Water fluxes in a 3D root system and in the soil for a soil profile with a wet top layer over a dry layer. (a): Soil water content; (b): uptake density (sink term) in horizontal planes and axial root flow; (c): xylem water potential, soil water potential and flux in the soil (black arrows).

water potential changes at the soil root interface that result from water uptake and water flow in the soil profile, the flow in the root system must be coupled to the flow equation in the soil (Javaux et al., 2008):

$$\frac{\partial \theta}{\partial t} = \nabla \cdot \mathbf{K} \nabla h_{T,soil} - S(\mathbf{x}) \quad (9)$$

where θ is the volumetric water content, $\mathbf{K}$ is the soil hydraulic conductivity tensor [m s^{-1}] and $S(\mathbf{x})$ is the sink term [$\text{m}^3 \text{m}^{-3} \text{s}^{-1}$] that represents the uptake of water per bulk volume of soil by all root segments in an infinitesimal soil volume $d\Omega$ around $\mathbf{x}$ (positive for uptake, negative for water efflux). When the soil water potentials do not vary horizontally and soil water flow is only in the vertical direction, the flow equation can be written in a one-dimensional form as:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z} \left[K \left[\frac{\partial h_{p,soil}}{\partial z} + 1 \right] \right] - S(z) \quad (10)$$

where z is the vertical co-ordinate, $h_{p,soil}$ is the soil water pressure potential, and $S(z)$ represents the averaged uptake in a soil layer with infinitesimal thickness dz at depth z . To solve the equations, functions that relate θ and K with $h_{p,soil}$, i.e., the soil hydraulic functions, are required. The averaged sink term distributions show a similar sensitivity to the ratio of the radial to axial root segment conductance as the single root uptake. When soil water potentials are uniform and when the ratio of radial to axial conductivity is sufficiently small, the root uptake profile corresponds with the root length density distribution. For a large axial conductance, and consequently a large root system conductance, small decreases in soil water potential near the soil surface where uptake is initially larger due to the greater root density are compensated by a larger uptake deeper in the soil profile so that the root water uptake profile becomes more uniform with depth (Fig. 7a). For smaller axial conductances, the water uptake is initially concentrated near the soil surface (Fig. 7c) and then shifts downwards when the upper soil layer dries out. This shows that root hydraulic properties, root architecture, and the soil water potential profile determine the root water uptake distribution with depth and that this distribution differs from the root density profile.

The uptake integrated over all layers in the root zone corresponds with the plant transpiration rate (assuming that there is no water storage capacity in the plant):

$$T_{act} = \int_{L_{root}}^{z_{surf}} S(z) dz \quad (11)$$

where L_{root} is the depth of the bottom of the rootzone and z_{surf} is the elevation of the soil surface (m). When the soil is sufficiently wet and the soil hydraulic conductivity is considerably larger than the root radial conductivity, the water potential at the soil-root interfaces can be approximated by the bulk soil water potential and $S(z)$ can be described as (Couvreur et al., 2012):

$$S(z) = K_{rs}SUF(z)[h_{T,soil,eff} - h_{T,plant}] + K_{comp}SUF(z)[h_{T,soil}(z) - h_{T,soil,eff}] \quad (12)$$

where SUF is the 'standard uptake fraction' [m^{-1}] and $h_{T,soil,eff}$ is the effective soil water potential in the root zone, and K_{comp} a compensatory uptake conductance [s^{-1}]. $SUF(z)dz$ represents the fraction of the total root water uptake that is taken from a soil layer

Fig. 7 Vertical profiles of the horizontally averaged sink term (top row a–c) and xylem water potentials during a dry spell bottom row (d–f) that are simulated for a 3D root system with three different sets of root hydraulic properties: left column (a and d) high axial conductivity ($k_x = 4.32 \text{ cm}^3 \text{ d}^{-1}$), middle column (b and e) medium axial conductivity ($k_x = 4.32 \times 10^{-2} \text{ cm}^3 \text{ d}^{-1}$), and right column (c and f) low axial conductivity ($k_x = 4.32 \times 10^{-4} \text{ cm}^3 \text{ d}^{-1}$). The radial conductivity ($k_r = 1.73 \times 10^{-4} \text{ d}^{-1}$). Colors represent successive days and the dashed black line is the normalized root length density. From Draye X, Kim Y, Lobet G and Javaux M (2010) Model-assisted integration of physiological and environmental constraints affecting the dynamic and spatial patterns of root water uptake from soils. *Journal of Experimental Botany* **61**: 2145–2155.

with thickness dz at depth z when the soil water potential is uniform in the entire root zone. $h_{T\text{soil},\text{eff}}$ is a weighted average of the soil water potential in the root zone and the weights correspond with SUF :

$$h_{T\text{soil},\text{eff}} = \int_{L\text{root}}^{z\text{surf}} SUF(z) h_{T\text{soil}}(z) dz \quad (13)$$

Combining Eqs. (11), (12), and (13) and considering that the integral of SUF over the root zone equals one, $h_{T\text{soil},\text{eff}}$ can be used as the average soil water potential in the root zone in Eq. (5) to calculate the total root water uptake for a given plant water potential. Or, when the transpiration rate is known, e.g., the potential transpiration rate, the plant water potential can be calculated. It was shown by theoretical analysis of the flow equations in the root system, that the definition of $h_{T\text{soil},\text{eff}}$ as in Eq. (13) gives for all soil water potential distributions in the rootzone a correct estimation of the plant water potentials and transpiration rate, and that K_{comp} can be approximated by K_{rs} (Vanderborght et al., 2021).

The first term of Eq. (12) represents the uptake by the root system when the soil water potential is uniform in the root zone and equal to the effective soil water potential. The second term represents the uptake compensation by the root system for a heterogeneous distribution of soil water potentials. At depths where the soil is dry and $h_{T\text{soil}}(z) < h_{T\text{soil},\text{eff}}$, this term is negative and the uptake is reduced and vice versa for depths where the soil is wetter. At night when there is no uptake and the first term in Eq. (12) is zero, there is a negative uptake or an exudation of water by the root system, i.e., hydraulic root redistribution, in drier regions of the soil, and this redistribution is independent of the transpiration rate.

Because the root segment conductivities are assumed to be independent of the root water potentials and the water potential at the soil root interface is assumed to be equal to the bulk soil water potential, the relation between the transpiration rate and the difference between the soil and plant water potentials in Eq. (5) is linear. When transpiration is plotted versus $h_{T\text{soil},\text{eff}}$ and when stomata regulate the plant water potential so that it does not drop below a critical value, $h_{T\text{plant},\text{crit}}$ (i.e., perfect isohydric plant) then the maximal transpiration rate that is possible for a certain $h_{T\text{soil},\text{eff}}$ is given by a straight line with a slope K_{rs} (Fig. 8). The ratio of actual transpiration, i.e., the transpiration rate when the critical plant water potential is reached, to the potential transpiration rate is represented by a linear function with a steeper slope for lower potential transpiration rates. This implies that for a lower transpiration demand by the atmosphere, the plant reduces the transpiration rate at drier soil conditions than at higher potential transpiration rates. Interestingly, this corresponds to the stress functions proposed by Feddes et al. (1978), which describe the reduction in root water uptake as a function of soil water potential and potential transpiration.

Fig. 8 (Left) Maximal transpiration for a critical water potential in the plant $h_{T,plant,crit}$ and a given root system conductance, K_{rs} , versus the soil water potential, $h_{T,soil}$. When $h_{T,soil}$ reaches $h_{T,plant,crit}$, transpiration goes to zero. $h_{T,soil,crit,l}$ and $h_{T,soil,crit,h}$ represent the minimal soil water potentials for which the maximal plant transpiration can supply a, respectively, low and high potential transpiration or transpiration demand. (Right) Ratio of actual to potential transpiration versus soil water potential for a high and a low T_{pot} .

Fig. 9 Evolution of the root system conductance (K_{rs}) of a wheat crop from Feb. 11 until July, 24 in two soils (stony F1 and silty F2) and three water treatments (P1 dryout shelter, P2 rain fed and P3 irrigated). From Cai GC, Vanderborght J, Langensiepen M, Schnepf A, Huing H and Vereecken H (2018) Root growth, water uptake, and sap flow of winter wheat in response to different soil water conditions. *Hydrology and Earth System Sciences* 22: 2449–2470.

According to Eq. (12) and approximating K_{comp} by K_{rs} , K_{rs} and $SUF(z)$ are ‘sufficient’ properties of the root hydraulic system to describe the uptake from a soil profile. They are calculated directly from the root hydraulic architecture and the root segment hydraulic properties and translate the properties of the root system into its water uptake function. They are dynamic since they are related to root growth, root system development, and maturation. This growth depends on the soil properties and on the reaction of the plant to stress conditions. K_{rs} increases when the root system grows (Cai et al., 2018) (Fig. 9) and $SUF(z)$ is related to the root density in a certain layer but may differ from it, especially when the resistance to flow in the xylem is important (see Fig. 7).

Uptake including soil hydraulics

In dry soil, the low soil hydraulic conductivity leads to a drop in soil water potential along the radial water flow path from the bulk soil to the soil-root interface. Therefore, the bulk soil water potentials that are used in the soil water flow equation Eq. (9) should be scaled down to the water potentials at the soil root interface to calculate the flow into and within the root system (Eq. 7). This downscaling implies that the sink term in Eq. (9) depends not only on the root hydraulic properties but also on the soil. Downscaling can be done using ‘brute force’ by explicitly representing the 3D geometry of the roots in the 3D coupled soil-root model and treating the root system as an internal boundary in the soil domain instead of a distributed sink term. However, the computational costs to resolve the flow and water potential fields around 0.1 mm diameter roots are immense. Assuming that near the root segments, the flow in the soil is axisymmetric and perpendicular to the root and not influenced by gravity or water potential

gradients that drive the flow at a larger scale, a cylindrical rhizosphere can be constructed around the root and the flow in this rhizosphere can be described using a 1D axial symmetric flow equation:

$$\frac{\partial \theta_{rhizo}}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left[rK(h_{p,rhizo}) \frac{\partial h_{p,rhizo}}{\partial r} \right] + \nabla \cdot K \nabla h_{T,soil} \quad (14)$$

where θ_{rhizo} and $h_{p,rhizo}$ are the water contents and pressure heads in the rhizosphere. The term $\nabla \cdot K \nabla h_{T,soil}$ represents the change in water content in the rhizosphere per unit time due to divergence of flow at a larger scale. The inner boundary condition is defined at the root radius where the fluxes in the soil and root segments are matched, whereas the outer boundary is a no-flow boundary condition at half the average distance between root segments, which can be derived from the root length (RLD) density as:

$$r_{rhizo} = \sqrt{\frac{1}{\pi RLD}} \quad (15)$$

By averaging the rhizosphere model over the volume of the rhizosphere, the macroscale model is obtained, and the macroscale sink term is equal to the flow to the root divided by the volume to the rhizosphere:

$$S(\mathbf{x}) = \frac{2r_{root}}{r_{rhizo}^2 - r_{root}^2} K(h_{p,soil-root}) \frac{dh_p}{dr} \Big|_{r_{root}} \quad (16)$$

The rhizosphere part in Eq. (14) can either be solved numerically or analytically. Analytical solutions require some assumptions, such as the steady rate assumption, which means that the change in water content per time does not differ with the radial distance (i.e., $\frac{\partial \theta}{\partial t} = \text{constant}$). Then, the radial water flux at the soil root surface, q_r [m s^{-1}] and the sink term $S(\mathbf{x})$, can be expressed as:

$$q_r = -\frac{K_{soil-root} B}{r_{root}} (h_{p,soil} - h_{p,soil-root}) S(\mathbf{x}) = \frac{2K_{soil-root} B}{r_{rhizo}^2 - r_{root}^2} (h_{p,soil} - h_{p,soil-root}) \quad (17)$$

where $K_{soil-root}$ is an average soil conductivity [m s^{-1}] of the rhizosphere, B is a scaling factor, and $h_{p,soil}$ is the bulk soil water pressure head that corresponds with the averaged water content in the rhizosphere. $K_{soil-root}$ and B are obtained as in de Jong van Lie et al. (2008):

$$K_{soil-root} = \frac{\int_{-\infty}^{h_{p,soil}} K(h) dh - \int_{-\infty}^{h_{p,soil-root}} K(h) dh}{h_{p,soil} - h_{p,soil-root}} \quad (18)$$

$$B = \frac{2(\rho^2 - 1)}{1 - (0.53\rho)^2 + 2\rho^2(\ln \rho + \ln(0.53))}; \rho = \frac{r_{rhizo}}{r_{root}} \quad (19)$$

To calculate the sink term using Eq. (16) or Eq. (17), the soil water pressure potential at the soil-root interface, $h_{p,soil-root}$, must be known, which depends on the water flow in the root system. This implies that the flow equations in the root system and in the rhizosphere need to be coupled. By combining Eq. (17) with Eq. (7), the flow from the soil into the root xylem can be described as:

$$\frac{d}{dt} k_x \frac{dh_{T,xylem}}{dt} = -2\pi r_{root} \left(k_r^{-1} + \left(\frac{K_{soil-root} B}{r_{root}} \right)^{-1} \right)^{-1} (h_{T,soil} - h_{T,xylem}) \quad (20)$$

In contrast to Eq. (7), Eq. (20) is non-linear since $K_{soil-root}$ depends on $h_{T,soil}$ and $h_{T,xylem}$ ($h_{T,xylem}$ defines also $h_{T,soil-root}$ which is needed to calculate $K_{soil-root}$). Eq. (20) implies that the relation between plant water potentials, transpiration, root water uptake distribution, and bulk soil water potentials depends on both soil and root hydraulic properties. As an example, Fig. 10a and b shows a maize root system and the axial and radial root hydraulic properties as a function of the root segment ages. The maximal uptake that can be supplied by the root system, when the water potential in the root collar is $-16,000$ cm and the bulk soil water pressure head, $h_{p,soil}$ is uniform in the root zone, is plotted in Fig. 10c versus $h_{p,soil}$ for two different soils and for the case that the pressure at the soil-root interface is equal to $h_{p,soil}$. The slope of this curve corresponds to the soil-plant conductance, K_{rs} , defined in Eq. (5). When only the conductances in the plant are considered (which are assumed to be independent of the water potentials), this relation is linear. However, the non-linear soil hydraulic conductivity introduces a non-linearity in this relation, which is soil type dependent. For the silt loam soil, the soil plant conductance is constant with $h_{p,soil}$ and independent of the soil hydraulic conductivity for pressure heads larger than -2000 cm and decreases with decreasing $h_{p,soil}$. For the loamy sand soil, this decrease already starts at $h_{p,soil} = -100$ cm. Fig. 10d illustrates how these soil properties influence the ratio of the supply to demand, T_{act}/T_{pot} function for two T_{pot} values representing a large and a small demand.

The effect of root length density is illustrated in Fig. 10e and f. The root density was varied by considering more plants per surface area and a case with four times more plants per surface area led to a four times larger root density being simulated. A greater root density resulted in a larger K_{rs} and shifted the critical $h_{p,soil}$ at which the transpiration demand cannot be supplied by the soil-root system to more negative values.

Fig. 10 Maize root system (a), and the radial, k_r , and axial conductances, k_x , of primary and secondary root segments as a function of the root segment ages; maximal supply rates or uptake rates by the soil-root system as a function of the bulk soil water pressure, $h_p \text{ bulksoil}$, for a critical plant water potential of -160 m and in three different soils (different colored lines) (a) and (e), and supply-demand ratios (T_{act}/T_{pot}) as a function of $h_p \text{ bulksoil}$ for two demand rates (dashed vs. full lines) and for a normal planting density of maize (0.75 m and 0.15 plant distance between and within rows) (c) and (d) and a four times higher plant density (e) and (f).

Upscaling and reducing model complexity

The relationships between transpiration and soil water potential in Fig. 10 illustrate the impact of the hydraulic soil properties for a homogeneous distribution $h_{p,soil}$ in the root zone on the root water uptake. When parts of the root zone become too dry and $h_{p,soil-root}$ differs from $h_{p,soil}$, the upscaled linear flow equations in the root system (Eq. 12) cannot be used to calculate the uptake and the plant water potentials directly from the non-uniform distribution of $h_{p,soil}$. Upscaling of the sink term $S(x)$ associated with a single root segment and its rhizosphere (Eqs. 16 or 17) to the sink term of a horizontal soil layer $S(z)$ requires a few simplifying assumptions. The different formulations of $S(z)$ that are used in models come from different approximations and simplifications that were used in this upscaling. An assumption that is common to all models, and which is the basis of Eq. (15), is that root segments are uniformly distributed and parallel to each other and that the soil water potentials and xylem water potentials are uniform in the soil volume over which the sink term is upscaled. Under this assumption, the water flow from the soil to the root xylem in a certain layer can be calculated directly from the average soil and xylem potentials in the layer and the radial root and rhizosphere conductances (Eq. 20). The upscaling of the radial conductances, which are all in parallel for a certain soil volume/layer, is trivial and equal to taking the sum of the conductances of all segments in a layer. The approaches that are used to relate leaf water potentials (or root collar potentials), to the average xylem and soil water potentials and uptake from a soil volume or layer can be classified into two groups: the parallel and big root approaches. Selecting between these depends on how the root segments in a certain soil volume are assumed to be connected to the root collar and the plant (Fig. 11).

The parallel root system is representative of a fibrous root system in which roots take up water near the root tips. The big root system could be representative of a tap root system with horizontal laterals. The upscaled axial conductances are obviously related to the assumed architecture of the upscaled network and linking the axial conductances of root segments to upscaled conductances remains a challenge. The upscaled root hydraulic model in Eq. (12) corresponds with a parallel root system, but the parameters of this model, $SUF(z)$ and K_{rs} , can be calculated directly from the true 3D root architecture without making assumptions. The impact of the axial conductances is therefore included in these parameters and the model may represent quite accurately 3D root hydraulic architectures (Vanderborght et al., 2021). Knowing the upscaled radial conductances, an upscaled effective axial conductance can be derived directly for each depth z from $SUF(z)$ and K_{rs} using Eq. (12). The obtained upscaled radial and axial conductances for each soil layer represent the properties of the upscaled parallel root model which is coupled to the rhizosphere model to solve for water potentials at the soil-root interface and the sink term profile in the 1D soil water flow equation (Eq. 10). Often models are further simplified by neglecting the axial resistance to flow in the root system, so that the xylem water potential is everywhere the same and the difference between parallel and big root models disappears (de Jong van Lier et al., 2013). These upscaled models consider both the root and soil hydraulic properties to calculate root uptake. Because of the non-linearity of the rhizosphere equation, the sink term needs to be solved iteratively, which increases the computational effort. Another simplification neglects resistance to flow in the rhizosphere and uses Eq. (12) to calculate the uptake from the soil water potentials directly without iterations. This approach only considers the root hydraulic properties and is appropriate when the soil is sufficiently wet but may overestimate the capacity of the root system to dry out the soil. It also leads to an overestimation of hydraulic redistribution and exchange into dry soil layers via the root system. As the approaches mentioned above consider water flow in the root system, they reproduce phenomena such as

Fig. 11 Resistance networks considered in the parallel and big root systems and corresponding root system architectures. The parallel root system corresponds with a fibrous root system where water uptake takes place only near root tips, whereas a big root system corresponds with a taproot system with horizontal laterals.

root water uptake compensation and hydraulic lift. The local water uptake at a certain depth does not depend solely on soil water potentials at that depth but is also influenced by the water potential distribution in the entire root zone.

A further set of models do not simulate water flow in the root system and describe water uptake at a certain depth as a function of the atmospheric demand and the soil water potential at that depth. Using a similar formulation as Eq. (12), the sink term is described as:

$$S(z) = \alpha(h_{p,soil}(z), T_{pot})SUF(z)T_{pot} \quad (21)$$

where $SUF(z)$ is the normalized uptake distribution when the soil is sufficiently wet and α is a stress factor that varies between 0 and 1, which depends on the local soil water pressure head and the potential transpiration rate. $SUF(z)$ is mostly derived from the normalized root length density and α is a piecewise linear function with threshold soil water pressures, $h_{p,soil,crit}$, that depend on T_{pot} (Feddes et al., 1978).

$$\alpha(h_{p,soil}) = \frac{h_{p,soil} - h_{T,plant,crit}}{h_{p,soil,crit}(T_{pot}) - h_{T,plant,crit}} \text{ for } h_{T,plant,crit} < h_{p,soil} < h_{p,soil,crit}(T_{pot}) \quad (22)$$

The functional form of the stress factor α corresponds with supply functions that are derived using linear root hydraulics (see Fig. 8b). However, α is expressed in terms of soil water pressure heads whereas root hydraulics use total soil water potentials, which include elevation. The α function has been derived from observations of crop transpiration and root zone soil water potentials to obtain crop specific parameters. The α -function lumps the impact of the root system and soil hydraulic properties into one single function. Variations in hydraulic properties of root systems and of the relation between stomatal closure and leaf water potentials of different crops are depicted in different critical pressure heads for different crops (Table 2).

Root systems of a certain crop vary considerably with crop development and in reaction to soil and environmental conditions. Considering only root hydraulics, the critical soil water pressure head at which the uptake starts declining is obtained from:

$$h_{p,soil,crit} = \frac{T_{pot}}{K_{rs}} + h_{T,plant,crit} \quad (23)$$

For the example of the crop with $K_{rs} = 2 \times 10^{-4} \text{ d}^{-1}$ and $h_{T,plant,crit} = -150 \text{ m}$, $h_{p,soil,crit}$ would be -50 m for a daily averaged transpiration rate of 5 mm d^{-1} (which corresponds to a peak transpiration at midday of 20 mm d^{-1}), which is much more negative than the values listed in Table 2. The relatively high threshold pressure heads in Table 2, which are considerably larger than thresholds that are derived from root hydraulics (see also Fig. 10), reflect the impact of the soil hydraulic resistances on the stress functions. But, parameterizations of the α -stress function do not consider soil hydraulic properties.

The RWU modeled by Eq. (21) at a certain depth is not influenced by soil water pressures at other depths and does not increase when root water uptake decreases at other depths where the soil dries out. Redistribution of RWU and RWU compensation are hence not considered. To account for these processes without explicitly simulating flow in the root system, an additional stress index ω that quantifies the overall stress in the root zone was introduced (Jarvis, 1989):

$$\omega = \int_{L_r}^0 \alpha(h_{p,soil}(z), T_{pot})SUF(z)dz \quad (24)$$

When this stress index is larger than a critical index, ω_c , local reduction in water uptake due to local water stress can be fully compensated by redistributing the local uptake so that the supply, T_{act} , satisfies the demand, T_{pot} . The total uptake is described by the following equation (see Fig. 12):

$$T_{act} = \omega \frac{T_{pot}}{\max[\omega, \omega_c]} \quad (25)$$

For $\omega_c = 1$, the root system does not compensate whereas for $\omega_c \rightarrow 0$, the root system extracts all soil water at the potential transpiration rate until the water content in the root zone reaches the wilting point. When root water uptake compensation is considered, the model simulates that plants extract more water at a potential rate and dry out the soil more before transpiration

Table 2 Critical water potentials of the α -stress function (Eq. 22) (Wesseling, 1991).

Crop	$h_{p,soil,crit}$ (large T_{pot}) (m)	$h_{p,soil,crit}$ (small T_{pot}) (m)	$h_{T,plant,crit}$ (m)
Potatoes	-3.2	-6.0	-160
Sugar beet	-3.2	-6.0	-160
Wheat	-5.0	-9.0	-160
Pasture	-2.0	-8.0	-80
Corn	-3.25	-6.0	-80

Fig. 12 Relative transpiration (T_{ac}/T_{pot}) versus stress index ω (Eq. 24) predicted by a model that considers root water uptake compensation: Eq. (25). The solid line represents T_{ac}/T_{pot} for a critical ω_c of 0.5 and dashed line represents T_{ac}/T_{pot} when there is no compensation, i.e., $\omega_c = 1$. From Jarvis NJ (2011) Simple physics-based models of compensatory plant water uptake: Concepts and eco-hydrological consequences. *Hydrology and Earth System Sciences* 15: 3431–3446.

is reduced. For a given stress level $\omega < \omega_c$, the simulated uptake is a factor ω_c^{-1} larger when compensation is considered. The local root water uptake is described by either:

$$S(z) = \alpha(h_{p,soil}(z), T_p)SUF(z) \frac{T_{pot}}{\max[\omega, \omega_c]} \quad (26)$$

or

$$S(z) = \left(\frac{\alpha(h_{p,soil}(z), T_{pot})}{\omega_c} - \max\left[\frac{\omega}{\omega_c}, 1\right] + 1 \right) SUF(z)T_{pot} \quad (27)$$

Both formulations predict the same uptake distribution when transpiration is lower than T_{pot} ($\omega < \omega_c$) but deviate from each other when the transpiration demand can be supplied ($\omega > \omega_c$). Eq. (27) was derived using a mechanistic description of water flow in the rhizosphere to root segments assuming that the root hydraulic conductance was large compared to the soil hydraulic conductance (Jarvis, 2011). In contrast to Eq. (26), which predicts $S \geq 0$ for all conditions, Eq. (27), predicts hydraulic lift and water redistribution via the root system, i.e., $S < 0$, at depths where $\alpha + \omega_c - \omega < 0$. This occurs only when plants are not stressed, i.e., $\omega > \omega_c$, and at locations where the soil is considerably drier than the mean soil water content, $\alpha < \omega$. Through the mechanistic derivation of Eq. (27), α , ω , and SUF are related to the soil and root system hydraulic properties and to the transpiration demand, T_{pot} , and can be derived from, in theory, measurable properties. Jarvis (2011) derived ω_c from resistances to flow in the rhizosphere while neglecting the flow resistance in the root system, whereas for relatively wet soil conditions, the latter is much larger than the former (see Fig. 2). Consequently, root water uptake redistribution under wet soil conditions was probably overestimated. Simply replacing the soil by root conductivities in the relation derived by Jarvis (2011), which would be more appropriate for wet soil conditions but less for dry conditions, gives the following expression for ω_c :

$$\omega_c = - \frac{T_{pot}}{K_{rs}h_{T,plant,crit}} \quad (28)$$

The critical stress index can be interpreted as the ratio of the potential transpiration to the maximal water supply to the canopy when the soil is saturated. When root density is considered a proxy for SUF and the soil profile is split into a wet or saturated domain and a dry domain, ω_c represents the minimal fraction of roots in saturated soil that is required to supply the potential transpiration. The smaller this ratio or fraction, the larger is the potential of the root system to redistribute water uptake and supply the water demand. Considering the crop with $K_{rs} = 2 \times 10^{-4} \text{ d}^{-1}$ and $h_{T,plant,crit} = -150 \text{ m}$, ω_c drops from 1 (no compensation) at $T_{pot} = 30 \text{ mm d}^{-1}$ to $\omega_c = 0.33$ for $T_{pot} = 10 \text{ mm d}^{-1}$. Mostly, ω_c is treated as a fixed parameter and is obtained from model fitting. When the dependence of ω_c on climate, soil, and root system dynamics is not considered, the fitted parameter should not be used to make predictions outside the range of conditions that were represented in the fitted dataset. Root hydraulic considerations show that ω_c and threshold pressures of the α -functions are related to each other since they depend on the same root hydraulic parameters. This implies that ω_c and α -function parameters should be derived together and not sequentially whereby, for example, parameters of the α function were derived first from fitting model simulations that did not consider compensation, i.e., assuming $\omega_c = 1$, to observations.

When ω_c is small, the root system can redistribute the water uptake within the root zone so that the supply rate does not depend strongly on the distribution of water in the root zone. In such a case, the reduction of water uptake compared to non-stressed

Fig. 13 T_{act}/T_{pot} simulated by a model that considers root water uptake compensation (gray dots) and by a model that does not consider root water uptake compensation (colored dots, color refers to the day of year, doy) and plotted versus the mean water saturation in the root zone $\langle \Theta \rangle_{root}$. The trajectory depicts a specific time series from June to the end of August and the inset shows the simulated T_{act} and infiltration during this period. From Schlüter S, Vogel HJ, Ippisch O and Vanderborght J (2013) Combined Impact of soil heterogeneity and vegetation type on the annual water balance at the field scale. *Vadose Zone Journal* 12: 1–17.

conditions can be described as a function of the average water content in the root zone. Fig. 13 shows simulated transpiration rate reductions in grassland that are plotted versus the average soil moisture content in the root zone and that are obtained using a model that does or does not ($\omega_c = 1$) consider root water uptake compensation. When compensation is considered, the reduction in transpiration occurs at lower water contents and the relation between the reduction factor and average soil moisture is less scattered.

This approach is used in 0D (zero-dimensional) soil water balance models that are used for irrigation planning (Doorenbos and Kassam, 1979), or in ecohydrology (Rodríguez-Iturbe and Porporato, 2004). It can describe the change in total water stored in the root zone over time as a function of different in- and outflows, which themselves are functions of the stored water content. The reduction functions consider a threshold fraction of the total plant-available water in the root zone (or its opposite, a threshold depletion fraction). For water contents above this threshold, the transpiration demand can be met by the supply. For water contents below this limit, the reduction factor is described as a decreasing function, either linear or convex, with decreasing water content (or increasing depletion factor). The threshold water content depends on the crop or vegetation type, transpiration demand, and soil type. In line with the process based models, greater water content (lower depletion factor) thresholds are used for larger transpiration rates, for vegetables than for grain crops (although no explicit link is made to the root system but increased thresholds would correspond to crops having a smaller root system conductance, shallow rooting depths and small densities) and for fine textured rather than coarse textured soils (Fig. 14). Although threshold soil water potentials are more negative for fine than for coarse soils (see Fig. 10d and f), the water contents are greater at these thresholds in fine-textured soils than in soils of coarse texture.

Uptake in saline soils

In saline soils, the osmotic potential is an important component of the total soil water potential. Since water flowing from the soil-root interface to the xylem must cross a cell membrane and since cell membranes show selectivity for transport of water compared to transport of ions, differences in osmotic potential between the xylem and the soil root interface drive water fluxes between the soil and the xylem. In spring before leaf burst and before the establishment of the transpiration stream, osmotic potentials in the xylem of tree roots are reduced to absorb water from the soil and induce a sap flow under a positive turgor towards the leaf buds. In saline soils, the low osmotic potentials in the soil water reduce the flow from the soil to the xylem. The leaky-pipe flow equation for a single root segment considering differences in osmotic potentials between the soil and the root xylem is given by:

$$\frac{d}{dt} k_x \frac{d(h_{p,xylem} + z)}{dl} = -2\pi r_{root} k_r (h_{p,soil-root} - h_{p,xylem} + \sigma(h_{o,soil-root} - h_{o,xylem})) \quad (29)$$

where σ is a ‘membrane reflection’ coefficient that varies between 0 (the membrane is not selective or is leaking and ions can pass like water) and 1 (membrane is perfectly selective and ions cannot pass) (Hopmans and Bristow, 2002). Gradients in osmotic

Fig. 14 Transpiration reduction function based on the available soil moisture relative to the maximal plant available soil moisture in the root zone, Θ , which is the ratio of $(\theta - \theta_w)/(\theta_{FC} - \theta_w)$ where θ_w is the water content at the permanent wilting point ($h_{p,soil} = -150$ m) θ_{FC} is the water content at ‘field capacity’. After Doorenbos J and Kassam AH (1979) *Yield Response to Water*. FAO: Rome.

potential drive a water flow when the mobility of ions is restricted compared to the mobility of water molecules. This is generally not the case within the soil or within the xylem, so water flow in the soil or in the xylem does not depend on gradients in osmotic potential. That is why the gradient in osmotic potential is not included in the left-hand side of Eq. (29). To describe the osmotic potentials in the soil and in the xylem, salt concentrations need to be predicted (Eq. 4) and transport equations that describe the transport of solutes need to be solved. As the transport of salts is driven by water fluxes and the water fluxes, in turn, depend on the salt concentrations, flow and transport in the soil-plant system are two-way coupled. Schröder et al. (2013) developed and used a model that simulates 3D salt transport in a coupled soil-root architecture model and accounts for the impact of osmotic potentials on root water uptake. They found that upscaled root hydraulic models that use total soil water potentials, including osmotic potential at soil root interfaces, can be applied directly to calculate root water uptake from saline soils. Upscaled soil models use bulk soil salinities or osmotic potentials to assess the impact of salinity on water uptake and use α -type stress functions similar to those used to evaluate the impact of low soil water pressure heads on root water uptake, e.g., Eq. (22) with $h_{p,soil}$ replaced by $h_{o,soil}$, (Maas and Hoffman, 1977) or using an S-shaped function (van Genuchten and Hoffman, 1984):

$$\alpha(h_{o,soil}) = \frac{1}{1 + \left(\frac{h_{o,soil}}{h_{o,soil,50}}\right)^p} \quad (30)$$

where p is a shape factor which is often taken to be 3 and $h_{o,soil,50}$ is the osmotic potential at which the potential transpiration is reduced by 50%. Because of salt accumulation, the osmotic potentials at soil-root interfaces are more negative than in the bulk soil and this difference increases with increasing advection flux towards the interface. This indicates that the salinity stress function should also show a sensitivity to the water uptake per root length with stress at less negative $h_{o,soil}$ for larger T_p and, or lower root length densities (de Jong van Lie et al., 2009). Another problem is mixed salinity and drought stresses. When water potentials at the soil-root interface are considered, the stress functions can be expressed in terms of the sum of $h_{p,soil-root}$ and $h_{o,soil-root}$. As the relations between bulk soil and interface potentials are different for osmotic and water pressure potentials, in theory a single stress function that depends on the bulk soil total water potential cannot be defined. This is in agreement with observations that the transpiration response shows different sensitivities to changes in $h_{p,soil}$ than to changes in $h_{o,soil}$. The transpiration response also shows interaction effects with a larger sensitivity to different salinity levels under wetter soil conditions than under drier conditions when the effect of $h_{p,soil}$ dominates. The following combined stress functions and variants of it have been proposed (Dudley and Shani, 2003; Homaei et al., 2002):

$$\alpha(h_{p,soil}, h_{o,soil}) = \frac{1}{1 + \left(\frac{h_{o,soil}}{h_{o,soil,50}} + \frac{h_{p,soil}}{h_{p,soil,50}}\right)^p} \quad (31)$$

or,

$$\alpha(h_{p,soil}, h_{o,soil}) = \alpha_p(h_{p,soil})\alpha_o(h_{o,soil}) \quad (32)$$

Different normalization factors for osmotic and pressure potential in Eq. (31) give different weight to the osmotic and drought stresses whereas Eq. (32) uses a multiplicative stress function. Because of the empirical nature of the stress functions, their parameters cannot be derived from direct measurements but must be derived from fitting functions of the soil pressure heads and osmotic potentials in the root zone to the observed plant responses. Therefore, it is difficult to define which functions and parameterizations are more appropriate. A mechanistic process model that combines water flow and solute transport in the soil root system may provide an alternative to obtain insight into the form of stress functions and how their parameters are related to soil and plant properties and to transpiration.

Conclusions and outlook

Water flow in the soil-plant system can be described according to the same physical laws and principles as the ones that apply to laminar flow in a tube or to flow in a porous medium. How much water can be taken up by plant roots from the soil profile without critical leaf water potentials being exceeded depends on the root and water distribution in the soil profile, and on the hydraulic properties of the soil and root segments. In root water uptake models that do not consider the detailed 3D water flow paths in the soil towards the root system, these dependencies are implicitly represented as a function of averaged soil water potentials or water contents in the root zone. The parameterization of these functions should therefore depend on both soil and root properties. A proper representation of the impact of root properties on these water uptake functions is important to identify root ideotypes based on model simulations. The concept of ideotypes is used in plant breeding and refers to a plant model which behaves or performs in a particular manner in a certain environment. Because plants grow, root systems and root distributions are, especially for annual plants, dynamic. This growth depends on environmental conditions so that plants and root systems show phenotypic plasticity, i.e., the same genotype develops differently in contrasting soil and climate conditions. Therefore, parameters of root water uptake functions should be coupled to the development and growth of a plant.

Abstract

This article summarizes the essential concepts and methodologies for estimating plant water and irrigation requirements. Reference evapotranspiration is defined relative to a reference crop with constant canopy characteristics, allowing to parameterize the surface and aerodynamic resistances to heat and vapor fluxes. Crop evapotranspiration is obtained using crop coefficients, which reflect the canopy differences relative to the reference crop. Both time-averaged and dual-crop coefficients are explained, together with corrections for climate and plant density. An adaptation aiming at estimating landscape water requirements is made by introducing the concept of the landscape coefficient. Finally, essential information on the soil water balance to estimate crop and landscape irrigation requirements is provided.

Key points

- Reference evapotranspiration (ET_o) represents the climatic demand for evaporation;
- The crop coefficient (K_c) accounts for the specific crop characteristics that deviate from the reference crop surface (height, canopy structure and density, and albedo);
- Standard K_c values can be transferred between locations after correction for climate;
- Crop ET is reduced when crops are under water stress or when plant density during the mid-phase is below full ground cover;
- The dual K_c refers to the sum of K_{cb} relative to the crop and K_e representing soil evaporation, with K_{cb} calculable from the fraction of ground cover and plant height;
- Landscape water requirements can be estimated with a similar procedure, where plant type, density and management water stress are taken into account, as well as local microclimate as influenced by plot size and surrounding areas;
- Irrigation water requirements aim at satisfying plant water requirements and can be determined from the soil water balance.

Introduction and main concepts

Crop water requirements (CWR) are defined as the depth of water [mm] needed to meet the water consumed through evapotranspiration (ET_c) by a disease-free crop, growing in large fields under non-restricting soil conditions including soil water and fertility, and achieving full production potential under the given growing environment. If *crop evapotranspiration* (ET_c) is defined as the rate of evapotranspiration [mm d^{-1}] of a given crop as influenced by its growth stages, environmental conditions, and crop management to achieve the potential crop production, then the CWR is the sum of ET_c for the entire crop growth period. When management or environmental conditions deviate from the optimal, then that rate of evapotranspiration requires adjustment to the prevailing conditions and is called *adjusted* or *actual crop evapotranspiration* ($ET_{c \text{ act}}$). Both CWR and ET_c concepts apply to either irrigated or rainfed crops.

For irrigated crops, the concept of *CWR* has to be complemented by that of irrigation water requirement (*IWR*), which is the net depth of water [mm] that is required to be applied to a crop to complement the natural water input to fully satisfy its specific crop water requirement. The *IWR* is the fraction of *CWR* not satisfied by rainfall, soil water storage and groundwater contribution. When it is necessary to add a leaching fraction to assure appropriate leaching of salts in the soil profile, this depth of water is also included in *IWR*. In practice, *IWR* has to be converted into gross irrigation requirements (*GIR*) to take into consideration the beneficial water use fraction (*BWUF*) of the irrigation systems utilized.

Crop evapotranspiration

The rate of evapotranspiration ET [mm d^{-1}] can be computed with the Penman-Monteith (PM) equation:

$$ET = \frac{1}{\lambda} \frac{\Delta (R_n - G) + \rho c_p (e_s - e_a)/r_a}{\Delta + \gamma (1 + r_s/r_a)} \quad (1)$$

where λ is the latent heat of vaporization [kg m^{-3}], $R_n - G$ is the net balance of energy available at the surface [$\text{MJ m}^{-2} \text{d}^{-1}$], $(e_s - e_a)$ represents the vapor pressure deficit (*VPD*) of air at the reference (weather measurement) height [kPa], ρ represents mean air density [kg m^{-3}], c_p represents specific heat of air at constant pressure [$\text{kJ kg}^{-1} \text{°C}^{-1}$], Δ represents the slope of the saturation vapor pressure-temperature relationship at mean air temperature [kPa °C^{-1}], γ is the psychrometric constant [kPa °C^{-1}], r_s is the bulk surface resistance [s m^{-1}], and r_a is the aerodynamic resistance [s m^{-1}].

The PM Eq. (1) can theoretically be utilized for the direct calculation of crop evapotranspiration when the crop specific surface and aerodynamic resistances are available. However, data for these crop characteristics are scarce for most crops.

The transfer of heat and vapor from the evaporative surface into the air in the turbulent layer above a canopy is determined by the aerodynamic resistance r_a [s m^{-1}] between the surface and the reference level above the canopy:

$$r_a = \frac{\ln \left(\frac{z_m - d}{z_{om}} \right) \ln \left(\frac{z_h - d}{z_{oh}} \right)}{k^2 u_z} \quad (2)$$

where z_m is the height of wind velocity measurements [m], z_h is the height of air temperature and humidity measurements [m], d is the zero plane displacement height [m], z_{om} is the roughness length relative to momentum transfer [m], z_{oh} is the roughness length relative to heat and vapor transfer [m], u_z is the wind velocity at height z_m [m/s] and k is the von Karman constant ($= 0.41$).

Eq. (2) assumes that the evaporative surface may be represented as a “big leaf” inside the canopy. However, exchanges in the top layer of the canopy, between heights $d + z_{om}$ and the crop height h [m] are important as sources of vapor fluxes, namely on complete cover crops with a wet soil surface. Adopting $d + z_{om}$ as the level of the evaporative surface can lead to overestimation of r_a and underestimation of r_s . Thus, as an alternative, r_a can be computed from the top of the canopy, h :

$$r_a = \frac{\ln \left(\frac{z_m - d}{z_{om}} \right) \ln \left(\frac{z_h - d}{h - d} \right)}{k^2 u_z} \quad (3)$$

Both parameters d and z_{om} depend upon the crop height, h , and canopy architecture. Information exists relating d and z_{om} to h . Most of these relationships are crop specific. More general functions also consider the leaf area index, *LAI*, or the plant area index (Table 1).

The height z_{oh} is estimated as a fraction of z_{om} , commonly $z_{oh} = 0.1 z_{om}$ for short and fully developed canopies. The factor 0.2 is often preferred for tall and partial-cover crops. However, there is relatively small impact on *ET* calculations from selecting a z_{oh}/z_{om} ratio between 0.1 and 0.2.

The surface resistance, r_s [s m^{-1}], for full-cover canopies is often expressed by

$$r_s = r_l / LAI_{eff} \quad (4)$$

where r_l is the bulk stomatal resistance of a well-illuminated leaf [s m^{-1}], and LAI_{eff} is the effective leaf area index [dimensionless], usually taken as 0.5 *LAI* for a full cover crop. r_l usually increases as a crop matures and begins to ripen. Typical values for r_l and r_s are listed in Table 2. The use of these equations for prediction of crop water requirements is difficult due to differences among varieties and crop management practices. Information on stomatal conductance or stomatal resistance available in the literature is mainly oriented to physiological or eco-physiological studies, rather than practical agricultural management. Information on bulk stomatal resistances and how they vary with climate or water availability is still scarce. Eq. (4) has the limitation of considering surface

Table 1 Relationships of d and z_{om} with crop height, h , and leaf area index, *LAI*.

d	z_{om}	Comment
$a_1 h$ (a_1 commonly ranges between 0.6 and 1)	$b_1 h$ (b_1 commonly ranges between 0.03 and 0.12)	Most studies on field crops
0.7 h	0.1 h	Complete cover crops
0.67 h	0.12 h	Dense vegetation canopies ($LAI > 2$)
$h \left[1 - \frac{2}{\alpha LAI} (1 - e^{-\alpha LAI/2}) \right]$	$h e^{\alpha LAI/2} (1 - e^{-\alpha LAI/2})$	Perrier (1982)

α is an adjustment factor for *LAI* with $\alpha = 2$ for $f \geq 0.5$ and $\alpha = [2(1 - f)]^{-1}$ for $f < 0.5$, with f being the proportion of *LAI* lying above $h/2$.

Table 2 Typical values of the leaf resistance per unit leaf area (r_l) and bulk stomatal resistance (r_s) for several canopy types.

Canopy type	r_l ($s\ m^{-1}$)	$r_{l\ min}$ ($s\ m^{-1}$)	r_s ($s\ m^{-1}$)	$r_{s\ min}$ ($s\ m^{-1}$)

Clipped grass (0.15 m)	100–150		80–120	70
Clipped and irrigated grass (0.10–0.12 m)	75	40	40–60	25–30

Parameters $r_{l\ min}$ and $r_{s\ min}$ are minimum daytime values when all environmental variables are optimum.

From Allen RG, Pruitt WO, Businger JA, Fritschen LJ, Jensen ME, Quinn FH (1996) Evaporation and transpiration. In: Wootton TP, Cecilio CB, Fowler LC, Hui SL, Heggen RJ (Eds.) ASCE Handbook of Hydrology. New York: ASCE, pp. 125–252.

resistance to be a pure physiological parameter while in reality it also includes an aerodynamic component that regulates the transport of water vapor inside the canopy.

In general, r_s varies according to:

$$r_s = r_a \left(\frac{\Delta}{\gamma} \beta - 1 \right) + (1 + \beta) \frac{\rho c_p VPD}{\gamma (R_n - G)} \quad (5)$$

where β is the Bowen ratio (the ratio between the sensible and latent heat fluxes). In this equation β plays the role of a water-stress indicator. This equation illustrates that weather variables interact and their influences are interdependent, thus adding to the difficulties in appropriately selecting r_s .

Current research work is focused on improving our ability to apply the PM equation or multi-layer ET models to specific agricultural crops. Meanwhile, the main use of the PM equation is to compute the reference evapotranspiration, with ET_c being determined using crop coefficients.

Reference evapotranspiration

Crop evapotranspiration, ET_c [mm], can be calculated by multiplying the reference evapotranspiration, ET_o [mm], by a dimensionless crop coefficient, K_c :

$$ET_c = K_c ET_o \quad (6)$$

Reference evapotranspiration aims at representing the climatic demand for evaporation, and is defined as the ET from an extensive surface of reference vegetation having a uniform, standardized height, that is actively growing, free of diseases and parasites and not short of water that completely covers the soil surface. Two crops have been used as reference: cool-season clipped grass and alfalfa.

The reference grass crop is a hypothetical crop with an assumed height of 0.12 m having a fixed surface resistance and an albedo of 0.23, closely resembling an extense surface of green grass of uniform height, actively growing and adequately watered. The reference evapotranspiration ET_o [mm d⁻¹] can then be easily computed with the PM Eq. (1) since the aerodynamic and surface resistance terms can be parameterized, resulting in the FAO-Penman-Monteith (FAO- ET_o or PM- ET_o) equation:

$$ET_o = \frac{0.408 \Delta (R_n - G) + \gamma C_n u_2 (e_s - e_a)}{\Delta + \gamma (1 + C_d u_2)} \quad (7)$$

where, in addition to variables defined for Eq. (1), T is mean daily air temperature [°C] and u_2 is wind speed [m s⁻¹], both at 2 m height. C_n and C_d are coefficients that differ with calculation time step. For daily computations, surface resistance is considered to be 70 s m⁻¹, which leads to a C_n value of 900 and $C_d = 0.34$. When using an hourly time-step computation, $C_n = 37$, while $C_d = 0.24$ during daytime ($R_n > 0$), assuming a surface resistance of 50 s m⁻¹; during nighttime, $C_d = 0.96$, given a r_s of 200 s m⁻¹.

The alfalfa reference ET (ET_r) is defined as the ET from full cover, well-watered, actively growing alfalfa with a standardized height of 50 cm. In this case C_n and C_d in Eq. (7) are 1600 and 0.38 respectively for daily calculations, and 66 and 0.25 (daytime) or 1.7 (nighttime) for hourly calculations. Due to the lower surface resistance and higher aerodynamic roughness of alfalfa, ET_r values are higher than ET_o and approximate near maximum rates of ET expected from well-watered vegetation.

The computation of the PM- ET_o equation parameters should follow the procedures described by Allen et al. (1998). However, in many parts of the world data on some weather variables are often missing from datasets or are of low or questionable quality, namely solar radiation, air humidity and wind speed. They can then be estimated using the procedures proposed by Allen et al. (1998), with this being the approach recommended for most situations. The Hargreaves equation is an alternative that is based on values of T_{max} and T_{min} only and may give acceptable ET_o estimates, namely in hyper-arid and arid conditions (Raziei and Pereira, 2013) particularly when properly parameterized (Paredes et al., 2020).

Recently the use of remotely sensed data, such as those retrieved from geostationary satellites, to estimate ET_o has become popular. Reanalysis products are another important source of atmospheric variables, such as shortwave radiation and temperature, which are made available at various spatial resolutions and allow high temporal sampling. Reanalysis has the advantage of providing consistent information that span along several decades (Paredes et al., 2021).

Crop coefficients

While ET_o represents the climatic demand on evaporation, the K_c represents the influence of the specific crop characteristics on crop evapotranspiration. Being little influenced by climate, standard values for K_c can be transferred between locations and climates. Values of K_c based on ET_o are generally 1.2–1.4 greater than those based on the alfalfa reference ET (ET_r) given the differences between the two reference crops. When using tabulated values the user must be careful in selecting the appropriate K_c values according to the reference ET equation used. Grass reference ET_o is considered throughout this article.

K_c represents an integration of the effects of three primary characteristics that distinguish the crop from the reference: crop height, h (affecting roughness and aerodynamic resistance); crop-soil surface resistance, r_s (related to leaf area, fraction of ground covered by vegetation, leaf age and condition, degree of stomatal control, and soil surface wetness); and albedo, α , of the crop-soil surface (influenced by the fraction of ground covered by vegetation and soil surface wetness).

Two K_c approaches are considered. The first uses a time-averaged K_c to include multi-day effects of evaporation from the soil. The second concerns the basal crop coefficient, to obtain crop transpiration, and another coefficient representing the evaporation from the soil.

The crop coefficient curve represents the changes in K_c over the length of the growing season (Fig. 1). Its shape relates to changes in the vegetation and ground cover during plant development and maturation that affect the ratio ET_c/ET_o . Shortly after planting of annuals, or the initiation of new leaves for perennials, the value for K_c is often small. The K_c increases from that initial value, $K_{c\text{ ini}}$, at the beginning of rapid plant development and reaches a maximum, $K_{c\text{ mid}}$, at the time of maximum or near maximum plant development, the mid-season period. During the late season period, as leaves begin to senesce, the K_c begins to decrease until it reaches a lower value, $K_{c\text{ end}}$, at the end of the growing period.

The form for the equation used in the dual K_c approach is:

$$K_c = K_s K_{cb} + K_e \quad (8)$$

where K_s is the stress reduction coefficient [0–1], K_{cb} is the basal crop coefficient [0–~1.4], and K_e is the soil water evaporation coefficient [0–~1.4]. K_{cb} represents the ratio ET_c/ET_o when the soil surface layer is dry but the average soil water content of the root zone is adequate to sustain full plant transpiration, thus representing the base-line potential K_c in the absence of evaporation from the soil (Fig. 2). K_s reduces the value of K_{cb} , when the soil water content is not sufficient. Eq. (8) requires the calculation of a daily soil water balance for the root zone.

A time-averaged K_c can be calculated as:

$$K_c = \overline{K_{cb} + K_e} \quad (9)$$

where $\overline{K_{cb} + K_e}$ represents the time averaged sum of the basal K_{cb} and the soil evaporation coefficient, K_e , given actual values or possible scenarios of soil wetting frequencies. Typical shapes for the K_{cb} , K_e and $\overline{K_{cb} + K_e}$ curves are shown in Fig. 2. When summed,

Fig. 1 Generalized crop coefficient curve from planting or initiation to harvesting or dormancy. From Allen RG, Pereira LS, Raes D and Smith M (1998) Crop evapotranspiration. In: *Guidelines for Computing Crop Water Requirements*. FAO Irrigation and Drainage Paper 56. Rome: FAO.

Fig. 2 Crop coefficient definitions showing the basal crop coefficient K_{cb} , which approximates canopy transpiration, the soil evaporation coefficient, K_e , and time-averaged $K_{cb} + K_e$ values. From Allen RG, Pereira LS, Raes D and Smith M (1998) Crop evapotranspiration. In: *Guidelines for Computing Crop Water Requirements*. FAO Irrigation and Drainage Paper 56. Rome: FAO.

the values for K_{cb} and for K_e represent the total crop coefficient, K_c . The time-averaged K_c is useful for planning, irrigation system design, and typical irrigation management or for large scale water balance studies. The dual K_c is best where effects of day-to-day variation in soil surface wetness are important to estimate the resulting impacts on daily ET_c , soil moisture profile, and deep percolation.

The single crop coefficient approach

A simple procedure may be used to construct the K_c curve (Fig. 3):

1. Divide the growing period into four general growth stages that describe crop phenology or development, and determine the lengths [days] of these stages. The four crop growth periods are:
 - i) *Initial*: for annual crops, duration of this phase is from planting date to approximately 10% ground cover. For perennials, the planting date is replaced by the "greenup" date, when initiation of new leaves occurs.
 - ii) *Crop Development*: from 10% ground cover to effective full cover, which often occurs at the initiation of flowering or when LAI reaches 3.
 - iii) *Mid-Season*: from effective cover to start of maturity, which is often indicated by the beginning of the ageing, yellowing or senescence of leaves, leaf drop, or the browning of fruit.
 - iv) *Late Season*: from start of maturity to harvest or full senescence. For some perennial vegetation in frost-free climates, crops may grow year-round so that the date of termination may be taken as the same as the date of "planting".
2. Identify the three K_c values that correspond to $K_{c\text{ ini}}$, $K_{c\text{ mid}}$ and $K_{c\text{ end}}$.
3. Connect straight line segments through each of the four growth stage periods

Fig. 3 Crop coefficient (K_c) curve and crop development stages definitions. From Allen RG, Pereira LS, Raes D and Smith M (1998) Crop evapotranspiration. In: *Guidelines for Computing Crop Water Requirements*. FAO Irrigation and Drainage Paper 56. Rome: FAO.

The length of crop growth stages are crop-specific and change duration with crop variety, planting date, cultivation practices and weather conditions, mainly air temperature. The length of crop growth stages may be predicted using cumulative degree-based equations or plant growth models.

The lengths of the initial and development periods may be relatively short for deciduous trees and shrubs that develop new leaves in the spring at relatively fast rates. The $K_{c\text{ ini}}$ should then reflect the ground condition prior to leaf initiation, including the amount of grass or weed cover, soil wetness, tree density, and mulch density. The length of the late-season period may be relatively short for crops harvested before senescence or for vegetation killed by frost. The value for $K_{c\text{ end}}$ should reflect the soil surface condition and that of the vegetation following plant death or harvest. Indicative lengths of growth stages are given in Allen et al. (1998). However, tabulated lengths may deviate from the actual ones, so local observations or information should be used to incorporate the effects of plant variety, climate, cultural practices and water and salinity stresses.

Values for $K_{c\text{ ini}}$, $K_{c\text{ mid}}$ and $K_{c\text{ end}}$ are listed in Tables 3 and 4 for various agricultural crops. Usually there is close similarity in K_c within the same crop group, since the plant height, leaf area, ground coverage and water management are generally similar.

The $K_{c\text{ ini}}$ values in Tables 3 and 4 are only approximate because they vary widely with soil wetting conditions and because ET during the initial stage for annual crops is predominantly evaporation from the soil. Therefore, estimates for $K_{c\text{ ini}}$ must consider the frequency of irrigation and rainfall that wet the soil surface as well as the presence of crop residue or plastic or organic mulches.

Evaporation from bare soil, E_s [mm d^{-1}], can be characterized as occurring in two stages (Fig. 4). During stage 1, termed the “energy-limited” stage and having a duration t_1 [days], moisture is transported to the soil surface at a rate sufficient to supply the potential rate of evaporation, E_{so} [mm d^{-1}], which is governed by energy availability at the soil surface. E_{so} can be estimated as:

$$E_{so} = 1.15 ET_o \quad (10)$$

where ET_o is averaged for the initial period [mm d^{-1}].

Stage 2 is termed the “soil water-limited” stage, where hydraulic transport of subsurface water to the soil surface is smaller, thus making $E_s < E_{so}$. A portion of the evaporation occurs from below the soil surface, and energy is supplied by transport of heat into the soil profile. E_s decreases as soil moisture decreases and can be assumed to be linearly proportional to the depth of water remaining in the evaporation layer.

When the time interval [days] between two successive wettings, t_w , is greater than t_1 , $K_{c\text{ ini}}$ can be determined from:

$$K_{c\text{ ini}} = \frac{TEW - (TEW - REW) \exp\left(\frac{-(t_w - t_1) E_{so} \left[1 + \frac{REW}{TEW - REW}\right]}{TEW}\right)}{t_w ET_o} \quad (11)$$

where REW is the readily evaporable water, corresponding to the depth of evaporation when stage 1 drying is complete [mm], TEW is the total evaporable water, i.e. the maximum evaporation depth when soil evaporation effectively ceases [mm]. From the concept of stage 1 drying results $t_1 = REW/E_{so}$.

When $t_w < t_1$, the entire process resides within stage 1, then

$$K_{c\text{ ini}} = E_{so}/ET_o \quad (12)$$

Where furrow or trickle irrigation is practiced, and only a portion of the soil surface is wetted, $K_{c\text{ ini}}$ in Eqs. (11) and (12) should be reduced in proportion to the average fraction of wetted soil surface, f_w (ranging from 0, when no rain or irrigation occur, to 1). Indicative values for f_w are shown in Table 5. The infiltration depth from irrigation, I_w [mm], should also be adjusted:

$$I_w = I/f_w \quad (13)$$

where I is the total irrigation depth [mm].

REW is greater for medium-textured soils and is smaller for coarse soils. Maximum values for REW (REW_{max}) may be predicted according to soil texture:

$$\begin{aligned} REW_{\text{max}} &= 20 - 0.15 (\text{Sa}) \quad \text{for Sa} > 80\% \\ REW_{\text{max}} &= 11 - 0.06 (\text{Cl}) \quad \text{for Cl} > 50\% \\ REW_{\text{max}} &= 8 + 0.08 (\text{Cl}) \quad \text{for Sa} < 80\%, \text{ Cl} > 50\% \end{aligned} \quad (14)$$

where Sa and Cl are the fractions of sand and clay in the soil [%].

The TEW value is governed by the depth of soil contributing to evaporation, z_e [100–150 mm]. The soil water-holding properties within this evaporative layer, the presence of a hydraulically limiting layer beneath it, the unsaturated hydraulic conductivity, the conduction of sensible heat into the soil, and any root extraction of water from the evaporative layer all influence TEW . An approximation to TEW_{max} is:

$$TEW_{\text{max}} = z_e (\theta_{FC} - 0.5 \theta_{WP}) \quad (ET_o \geq 5 \text{ mm d}^{-1}) \quad (15)$$

$$TEW_{\text{max}} = z_e (\theta_{FC} - 0.5 \theta_{WP}) \sqrt{\frac{ET_o}{5}} \quad (ET_o < 5 \text{ mm d}^{-1}) \quad (16)$$

where θ_{FC} and θ_{WP} are the soil water content at field capacity and wilting point [mm mm^{-1}]. Typical values for θ_{FC} and θ_{WP} are given in Table 6.

Table 3 Single (time-averaged) crop coefficients, K_c , basal crop coefficient, K_{cb} , for non-stressed well-managed vegetable crops in subhumid climates ($RH_{min} \approx 45\%$, $u_2 \approx 2$ m/s) for use with the FAO Penman-Monteith ET_o , and indicative mean maximum plant heights, h , maximum root depths, $z_{r\max}$, and depletion fractions for no stress, p .

Allen et al. (1998).

^aTEW = $(\theta_{FC} - 0.5 \theta_{WP}) Z_e$.

The average total water available for evaporation, W_a [mm], during each drying cycle is computed from the average depth [mm] added to the evaporative layer at each wetting:

$$W_a = P_{mean} + W_{ini}/n_w \quad (17)$$

where W_{ini} is the available soil water [mm] in the evaporation layer at the time of planting, n_w is the number of wetting events and P_{mean} is the average depth (mm) of water added to the evaporating layer at each wetting event. P_{mean} can be obtained with:

$$P_{mean} = \left(\sum P_n + \sum I_w \right) / n_w \quad (18)$$

but where each value of P_n and I_w must be limited to $P_n \leq TEW_{max}$ and $I_w \leq TEW_{max}$. The values for TEW and REW in Eq. (11) are calculated from TEW_{max} and REW_{max} as:

$$TEW = \min(TEW_{max}, W_a) \quad (19)$$

and

$$REW = REW_{max} \left[\min \left(\frac{W_a}{TEW_{max}}, 1 \right) \right] \quad (20)$$

When Eq. (14) to Eq. (16) are used, appropriate checking of results is required.

K_c adjustment for climate

The $K_{c \text{ mid}}$ and $K_{c \text{ end}}$ values in Tables 3 and 4 are valid for a standard subhumid climate where $RH_{min} = 45\%$ and $u_2 = 2 \text{ m s}^{-1}$. Under humid and calm conditions, the K_c for full-cover agricultural crops generally do not exceed 1.0 by more than about 0.05, because full-cover agricultural crops and the reference crop behave similarly regarding absorption of short-wave radiation, the primary energy source for evaporation under humid and calm conditions. Because the VPD is small under humid conditions, differences in ET caused by differences in r_a between the agricultural and the reference crop are also small, especially with low-to-moderate wind speeds. The values of K_c are thus less dependent on differences between the aerodynamic components of ET_c and ET_o . In contrast, under arid conditions, the effect of differences in r_a between the agricultural and the reference crop on ET_c become more pronounced because the VPD is often large. Hence, K_c will be larger under arid conditions, mainly for tall crops. Because the $K_{c \text{ mid}}$ and $K_{c \text{ end}}$ in Tables 3 and 4 represent conditions where $RH_{min} \approx 45\%$ and $u_2 \approx 2 \text{ m s}^{-1}$, when climatic conditions deviate from these values, the tabulated values need to be adjusted to the local climate:

$$K_c = K_{c \text{ (Table)}} + [0.04(u_2 - 2) - 0.004(RH_{min} - 45)] \left(\frac{h}{3} \right)^{0.3} \quad (21)$$

where $K_{c \text{ (Table)}}$ represents the $K_{c \text{ mid}}$ or $K_{c \text{ end}}$ taken from Tables 3 or 4, u_2 is the average daily wind speed at 2 m height [m s^{-1}], RH_{min} is the average daily minimum relative humidity [%], and h is the average plant height [m], with all averages referring to the midseason or the late-season period. Despite indicative values for h being presented in Tables 3 and 4, it is better to determine h from field observations. When crops are allowed to senesce and dry in the field ($K_{c \text{ end}} < 0.45$), no adjustment is necessary for $K_{c \text{ end}}$.

K_c for other vegetation and adjustment to non-pristine conditions

For large stands (larger than about 500–2000 m²) of vegetation not listed in the tables, for which the one-dimensional flux equations such as the PM Eq. (1) can be applied, a maximum upper limit on ET exists due to energy constraints. It is therefore possible to establish a maximum K_c for full cover vegetation, using:

$$K_{c \max} = \max \left\{ \left\{ 1.2 + [0.04 (u_2 - 2) - 0.004 (RH_{\min} - 45)] \left(\frac{h}{3} \right)^{0.3} \right\}, K_{cb} + 0.05 \right\} \quad (22)$$

where u_2 , $RH_{\min}$ and h are average values for the period considered, which may refer to the entire growth stage under consideration or, when more detailed computations are applied, be averaged for shorter periods (e.g., 5 days). $K_{c \max}$ ranges from about 1.05 up to 1.30.

The K_c values in Tables 3 and 4 represent potential water use by healthy, disease-free, and densely planted stands of vegetation, with adequate levels of soil water. When conditions are less than optimal, and crop height, plant density or leaf area index fall below full ground cover (that is, when $f_c < 0.90$ or $LAI < 3$), a reduction of the $K_{c \text{ mid}}$ and/or $K_{c \text{ end}}$ should be made, using:

$$K_c = K_{\text{soil}} + K_d \left[\max \left(K_{c \text{ full}} - K_{\text{soil}}, \frac{K_{c \text{ full}} - K_{\text{soil}}}{2} \right) \right] \quad (23)$$

where K_{soil} is the average K_c for bare soil, that should reflect the soil type and frequency of wetting as well as ET_o , and $K_{c \text{ full}}$ is the K_c for a full cover stand. K_d is a density coefficient, that will be further developed in a later section.

Other procedures, including remote sensing, may be used to estimate the K_c values for non-pristine conditions (Anderson et al., 2012; Pôças et al., 2020).

The dual crop coefficient approach

The basal crop coefficient, K_{cb} (Eq. 8) represents primarily the transpiration component of crop ET . Its use provides for separate adjustment for wet soil evaporation immediately following rain or irrigation events. This results in more accurate estimates of ET_c when computed on a daily basis. The K_{cb} curve has the same shape as the K_c curve (Fig. 1) and three values for K_{cb} are also required to draw the K_{cb} curve: $K_{cb \text{ ini}}$, $K_{cb \text{ mid}}$, and $K_{cb \text{ end}}$ respectively at the initial, mid-season and end-season. Recommended values for K_{cb} can be found in Tables 3 and 4, which must be adjusted for climate using a similar equation to Eq. (21), with the form:

$$K_{cb} = K_{cb(\text{Table})} + [0.04(u_2 - 2) - 0.004(RH_{\min} - 45)] \left(\frac{h}{3} \right)^{0.3} \quad (24)$$

The computation of the soil water evaporation coefficient K_e is based on the fact that evaporation from the soil is governed by the amount of energy available at the soil surface, which depends, in turn, on the portion of total energy that has been consumed by plant transpiration. Whenever the soil is wet and exposed to radiation, evaporation from the soil is predicted to occur at a maximum rate, thus K_e is also at a maximum. However, the sum $K_c = K_{cb} + K_e$ is limited by a maximum value of K_c ($K_{c \max}$, Eq. 22) following rain or irrigation. K_e decays after a wetting event depending on the cumulative amount of water evaporated from the surface soil layer. K_e can be calculated from

$$K_e = K_r (K_{c \max} - K_{cb}) \quad (25)$$

where K_r is the evaporation reduction coefficient [0–1]. Understandably, K_e is limited by the fraction of wetted soil exposed to sunlight, f_{ew} [0.01–1], so:

$$K_e \leq f_{ew} K_{c \max} \quad (26)$$

The method used to estimate evaporation from soil is similar to the one used to compute $K_{c \text{ ini}}$ where the evaporation rate is at the maximum rate until the depth of water depleted by evaporation, D_e [mm], equals REW (Fig. 4). When $D_e > REW$, the evaporation process is in stage 2, and its rate decreases in proportion to the remaining water. Therefore, K_r (Eq. 25) may be calculated as:

$$K_r = 1 \quad \text{for } D_e \leq REW \quad (27a)$$

$$K_r = \frac{TEW - D_e}{TEW - REW} \quad \text{for } D_e > REW \quad (27b)$$

D_e , the current depth of water depleted from the fraction of wetted soil exposed to sunlight, is computed from the daily water balance of the upper 100–200 mm of the soil:

$$D_{e \ i} = D_{e \ i-1} - (P_i - RO_i) - \frac{I_i}{f_w} + \left(\frac{K_e ET_o}{f_{ew}} \right)_i + T_{s \ i} \quad [0 \leq D_{e \ i} \leq TEW] \quad (28)$$

where P is the precipitation [mm], RO is runoff [mm] [$0 \leq RO \leq P$], I is the irrigation depth [mm], $(K_e ET_o/f_{ew})$ is the evaporation from the f_{ew} fraction of the exposed soil surface [mm], T_s is the transpiration from the f_w fraction of the evaporating soil layer [mm], and the subscript i refers to the day of estimation. To initiate the water balance, $D_e = 0$ immediately following a heavy rain or irrigation, or $D_e = TEW$ if a long time has passed since the last wetting. Precipitation (P) less than $0.2 ET_o$ may be ignored. For most applications $RO = 0$ and for most crops, except for very shallow-rooted crops, T_s can be neglected.

When the complete soil surface is fully wetted (e.g., by precipitation or sprinkler irrigation), $f_{ew} = 1 - f_c$, where f_c is the average fraction of ground covered by vegetation [0–0.99]. For irrigation systems where only a fraction of the soil surface is wetted, f_{ew} may be calculated as:

$$f_{ew} = \min(1 - f_c, f_w) \quad (29)$$

f_c should be observed in the field. When not observed, f_c can be estimated daily from:

$$f_c = \left(\frac{K_{cb} - K_{c \min}}{K_{c \max} - K_{c \min}} \right)^{1 + 0.5h} \quad (30)$$

$K_{c \min}$ is the minimum K_c for dry, bare soil [0.00–0.20]. The exponent " $1 + 0.5h$ " represents the effect of plant height on shading the soil and in increasing the K_{cb} . When programming, it is useful to set $(K_{cb} - K_{c \min}) \geq 0.01$ for numerical stability.

K_{cb} values are reduced when the soil water content in the root zone is too low to sustain transpiration at potential levels. The reduction is made through the water stress coefficient, K_s [0–1], that can be computed as:

$$K_s = \frac{\theta - \theta_{WP}}{\theta_p - \theta_{WP}} \quad (\theta < \theta_p) \quad (31)$$

where θ is actual average soil water content in the root zone [mm mm^{-1}] and θ_p is the threshold θ below which transpiration is decreased due to water stress [mm mm^{-1}]. By definition, $K_s = 1.0$ for $\theta > \theta_p$. The threshold θ_p is:

$$\theta_p = (1 - p) (\theta_{FC} - \theta_{WP}) \quad (32)$$

where p is the depletion fraction for no stress [0–1]. Indicative values can be found in Tables 3 and 4. The determination of K_s requires a daily balance of soil water content.

K_{cb} for unknown conditions and partial-cover crops

For vegetation with partial ground cover ($LAI < 3$) where the K_{cb} is not known, $K_{cb \text{ mid}}$ can be approximated as:

$$K_{cb \text{ mid}} = K_{c \min} + K_d (K_{cb \text{ full}} - K_{c \min}) \quad (33)$$

where K_d is a density coefficient, $K_{c \min}$ is the minimal basal K_c for bare soil (0.15 under typical agricultural conditions, but reaching values close to 0 when large periods without rainfall or irrigation occur) and $K_{cb \text{ full}}$ is the basal K_{cb} anticipated for the crop under full cover conditions ($LAI > 3$) under full water supply and corrected for climate, with:

$$K_{cb \text{ full}} = F_r \left(\left\{ \min[(1.0 + k_h h) 1.2] \right\} + 0.04(u_2 - 2) - 0.004(RH_{\min} - 45) \left(\frac{h}{3} \right)^{0.3} \right) \quad (34)$$

with $k_h = 0.1$ for tree and vine crops and tall field crops, and 0.2 for short crops and vegetables (Pereira et al., 2021c). The parameter F_r can be approximated by:

$$F_r \approx \frac{\Delta + \gamma(1 + 0.34u_2)}{\Delta + \gamma \left(1 + 0.34u_2 \frac{r_l}{r_{typ}} \right)} \quad (35)$$

where r_l and r_{typ} are the mean and the typical leaf resistance. r_{typ} is normally considered to be 100 s m^{-1} (Allen et al., 1998), with Mobe et al. (2020) using a value corresponding to the minimum unstressed canopy resistance when estimating K_{cb} values for apple orchards. F_r introduces an empirical adjustment for vegetation that exhibits more stomatal control than is typical of most agricultural crops, and plays an important role in the case of trees and vines. The standard value for F_r is 1 for annuals before leaf senescence, and decreases during late season due to leaf senescence. For perennials F_r also decreases during the late season but is also smaller than 1.0 when pruning and training control plant vigor. Pereira et al. (2021c) provide tables of F_r values for a wide variety of annuals and perennial crops.

For small, isolated stands, the internal boundary layer above the vegetation may not be in equilibrium with the underlying surface, particularly with well ventilated, tall trees. Small expanses of tall vegetation surrounded by shorter cover can result in a "clothesline effect" where the interchange between air and vegetation is much more efficient than over large expanses of homogeneous vegetation. In these cases, ET from isolated vegetation stands on a per unit area basis, may be significantly greater (1.6–2 times) than the corresponding ET_o computed for a grass reference (Allen et al., 1992), and $K_{cb \text{ full}}$ has to be increased beyond the value given by the equations above. On the other hand, the elevated ET from tall, narrow stands of vegetation can reduce ET

from adjacent shorter vegetation due to shading, blocking of wind and also by cooling and humidifying the air, so an integrated approach has to be considered where there is a mixture of vegetation types and heights, as developed for landscapes hereafter.

The density coefficient K_d describes the reduction in K_{cb} due to a reduction in the amount of vegetation. When LAI is known K_d can be approximated as

$$K_d = 1 - e^{-0.7 LAI} \quad (36)$$

where 0.7 is a common value for the light extinction coefficient inside the canopy. A different value can be used if more appropriate information regarding the specific crop is available.

When estimates of ground surface covered by vegetation are available, K_d may be estimated as:

$$K_d = \min \left(1, M_L f_{c\text{eff}}, f_{c\text{eff}}^{1/(1+h)} \right) \quad (37)$$

where $f_{c\text{eff}}$ is the effective fraction of soil covered or shaded by vegetation near solar noon [0.01–1], and M_L describes the effect of canopy density on shading and on maximum relative ET per fraction of ground shaded [1.5–2.0 during mid-season].

The calculation of $f_{c\text{eff}}$ depends on the plant spacing pattern. For tree crops and randomly planted vegetation, $f_{c\text{eff}}$ depends on the effect of the angle of the sun above the horizon (β) on the shaded area during the period of maximum ET (generally between 11:00 h and 15:00 h) (Fig. 5), with:

$$f_{c\text{eff}} = \frac{f_c}{\sin \beta} \leq 1 \quad (38)$$

For row crops, information is necessary to first compute the height to width ratio (HWR) of the crop row, namely the angle of plant row from east-west direction (Γ), the crop height (h) and the crop width as viewed from an east-west direction (Fig. 6), so that:

$$HWR = \frac{h \cos \Gamma}{\text{width}} \quad (39)$$

with $f_{c\text{eff}}$ being then calculated as:

$$f_{c\text{eff}} = f_c \left[\frac{HWR}{\tan \beta} \right] \quad (40)$$

The M_L multiplier imposes an upper limit on the relative magnitude of transpiration per unit area as represented by $f_{c\text{eff}}$ and is an attempt to simulate the physical limits on water flux through the plant (root, stem, leaves). It mostly ranges from 1.5 to 2.0 during the mid-season but as it depends on the canopy density and thickness it can be modified to fit the specific vegetation and the respective crop stage. Crops with more vertical production training systems, or with less leaf density or with leaves of very small dimension have lower M_L values. M_L values impact K_d mostly when $h > 3.0$ and $f_c < 0.60$, so careful parameterization has to be performed when dealing with high trees or sparse crops (Pereira et al., 2021c).

Fig. 5 Schematic illustration of the calculation of $f_{c\text{eff}}$ from f_c and β (Allen and Pereira, 2009).

Fig. 6 Schematic representation of a row crop showing main canopy characteristics—width, height and angle Γ of plant row from an east-west direction that are used for the calculation of the height to width ratio (HWR) and effective ground cover $f_{c\ eff}$ for row crops. Adapted from Allen RG, Pereira LS, Raes D and Smith M (1998) Crop evapotranspiration. In: *Guidelines for Computing Crop Water Requirements*. FAO Irrigation and Drainage Paper 56. Rome: FAO.

In orchards it is common to have natural vegetation or grass covering the ground with the purpose of enhancing infiltration of rainfall and reducing soil erosion. To consider the contribution of the ground cover to the total evapotranspiration, K_{cb} can be estimated as:

$$K_{cb} = K_{cb\ cover} + K_d \left(\max \left[K_{cb\ full} - K_{cb\ cover}, \frac{K_{cb\ full} - K_{cb\ cover}}{2} \right] \right) \quad (41)$$

where $K_{cb\ cover}$ is the K_{cb} of the ground cover in the absence of tree cover. The second term of the $\max$ function sets the estimated K_{cb} to half the difference between $K_{cb\ full}$ and $K_{cb\ cover}$ when this difference is negative, and accounts for the effects of the shading of the active ground cover by the taller trees. The value of $K_{cb\ cover}$ should be chosen adequately so as to reflect the density and vigor of the surface cover on sunlit areas.

Updated values for $K_{cb\ ini}$, $K_{cb\ mid}$, $K_{cb\ end}$, $K_{c\ ini}$, $K_{c\ mid}$ and $K_{c\ end}$ are listed in Tables 7–10 for various tree crops and plant densities. Usually there is close similarity in K_c within the same crop group. Full information regarding the crops and the tabulated values can be found in Pereira et al. (2020, 2021a, 2021b, 2021c) and Rallo et al. (2021).

Landscape water requirements

Landscapes are big water users in urban and residential areas, creating the need for more rational and efficient water use as competition for limited water resources increases (Pereira et al., 2009). Procedures to estimate water use and set objectives regarding irrigation of these surfaces have recently been adapted from those already developed for agricultural crops. These procedures take into account the fact that landscapes deviate from agricultural crops in several aspects:

- landscapes most often do not have the dimensions needed for the internal boundary layer above the vegetation to be in equilibrium with the underlying surface, as is implied in the Penman-Monteith equation. Therefore, compensating adjustments are necessary to account for effects of local surroundings on plant water use;
- landscapes often comprise mixtures of types of vegetation, with different heights, structure and resistance to water stress, and have non-uniform spatial configurations;
- contrary to agricultural crops, where irrigation aims at maximizing biomass production /marketable yield, landscape irrigation aims at maintaining an appealing appearance. Many plants species used in landscaping can tolerate some degree of water stress without impacts on health, longevity and appearance and thus deficit irrigation is often adopted, contrary to agricultural crops.

Table 7 Single (time-averaged) crop coefficients, K_c , basal crop coefficient, K_{cb} , for non-stressed well-managed vine, fruit crops, berries and hop in subhumid climates ($RH_{min} \approx 45\%$, $u_2 \approx 2$ m/s) for use with the FAO Penman-Monteith ET_o , and indicative mean maximum plant heights, h , maximum root depths, $z_{r\max}$, and depletion fractions for no stress, p .

(Allen et al., 1998; Allen and Pereira, 2009; Rallo et al., 2021; Pereira et al., 2021c).

^{a1} The K_c *ini* in the Table are only indicative and valid for typical irrigation management and soil wetting frequency.

^bThe larger values for $z_{r\ max}$ correspond to rainfed conditions.

^cThe tabulated value for p must be corrected when $ET_c \neq 5\text{ mm d}^{-1}$ using $p = p_{\text{table}} + 0.04 (5 - ET_c)$.

For landscapes, distinction should be made between target ET (ET_L) and actual ET ($ET_{L\ act}$) values. ET_L is based on minimum ET levels, relative to climate, necessary to sustain a healthy, attractive landscape while $ET_{L\ act}$ is based on landscape type and on actual water availability (Allen et al., 2007). When the landscape receives more water than that required by the target that includes intentional stress, then actual ET values may exceed target ET values. Under these conditions, landscape vegetation is able to exploit the additional available water. In contrast, when actual water stress levels are higher than the targeted ones the actual ET is lower than target ET values.

The water use from a landscape (ET_L), using an analogy with agricultural crops, can be estimated by

$$ET_L = K_L ET_o \quad (42)$$

where K_L is the landscape coefficient. An innovative approach to K_L was first developed by Costello et al. (2000), labeled as the WUCOLS (Water Use Classification of Landscape Species) method, and later modified by Romeo and Dukes (2010) for the LIMP (Landscape Irrigation Management Program), where the K_L is decoupled into four other coefficients that represent the factors that impact ET from landscapes—vegetation type, density, local climate, and soil water management. A similar approach to K_L was adopted by the Irrigation Association (IA) (2011). The multi-component decoupling method facilitates its application to the very different types of vegetation and environments that can be found in landscapes.

In this approach, the K_L has the form.

$$K_L = K_v K_d K_{mc} K_{sm} \quad (43)$$

From: Allen RG, Pereira LS, Raes D and Smith M (1998) Crop evapotranspiration. In: *Guidelines for Computing Crop Water Requirements*. FAO Irrigation and Drainage Paper 56. Rome: FAO; Rallo G, Paço TA, Puig-Sirera A, Paredes P, Massai R, Provenzano G, Pereira LS (2021) Updated single and dual crop coefficients for tree and vine fruit crops. *Agricultural Water Management* **250**: 106645; Pereira LS, Paredes P, Melton F, Johnson L, Mota M and Wang T (2021c) Prediction of crop coefficients from fraction of ground cover and height: Practical application to vegetable, field and fruit crops with focus on parameterization. *Agricultural Water Management* **252**: 106663.

where K_v is a vegetation species factor (0.7–1.2), K_d is a vegetation density factor (0–1.0), K_{mc} is a microclimate factor (0.5–1.5), and K_{sm} is a managed water stress factor (0–1.0). Despite the apparent complexity of this approach, it can be easily implemented as each coefficient can be estimated separate from the others based on visual observation of the landscape, coupled with management objectives. Upper bounds of 1.00 for the modifying coefficients K_d and K_{sm} simplify their estimation and reduce uncertainties.

Though the method has been developed for landscapes, it can also be used to estimate ET of riparian strips and land corridors, or of small farms, undulating terrain, and multiple microclimates within an agricultural area.

The vegetation coefficient K_v is the maximum K_L expected for a specific single or mixture of plant species under full or nearly full ground cover, full soil water supply and where no microclimate adjustments are required and is estimated as:

$$K_v = \frac{ET_v}{ET_{o \text{ mc}}} \quad (44)$$

where $ET_{o \text{ mc}}$ is a local reference evapotranspiration if it were possible to measure weather data over a well-watered grass surface to determine ET_o in the local climate, and ET_v is the ET of the specific single or mixture of plant species with full ground cover (>70–80% of the ground covered or shaded by vegetation), where there are no microclimate adjustments required and under full soil water supply. The K_v is thus the equivalent of the K_c for agricultural crops, and Tables 3, 4, 7–10 can assist in choosing an adequate value given the specific plant structure and height. Also, many types of landscape vegetation tend to exhibit similar values for K_v due to similarities in height, total leaf area, stomatal response, and energy absorption. Therefore, condensed tables of typical values for general species types have been developed to provide general estimates for K_v (Table 11). Turfgrass coefficients are generally less than 1.0, contrary to what could be expected, since these surfaces are normally kept shorter than the 12 cm of the reference grass surface used to estimate ET_o .

The vegetation coefficient is not an equivalent to the plant or species coefficient (K_{sp}) considered by the WUCOLS model, as the K_{sp} is based on the water needs to maintain health and appearance, thus including a stress tolerance factor. Therefore, when using tabulated values, it is important to confirm the model they are to be used with.

Table 11 General vegetation factors (K_v) for general plant types for coverage (shading) of the ground >70–80% and full water supply.

Type of vegetation	K_v
Trees	1.15
Shrubs, desert species	0.70
Shrubs, non-desert species	0.80
Groundcover	1.00
Annuals (flowers)	0.90
Mixture of trees, shrubs, and groundcover	1.20
Turfgrass (cool season and warm season)	0.90

Allen et al. (2020).

Landscapes can vary considerably in terms of vegetation density, as there can be great variation in plant spacing, size, and maturity. The *density coefficient*, K_d , already described above (Eq. 37), can be used to correct the density impacts on ET based on fraction of ground cover, height and stomatal control of the specific vegetation.

Reference ET_o , which represents weather-based effects on ET , constitutes a regional estimate of reference evapotranspiration based on measured weather data from an open, vegetated area. ET from small sized patches of vegetation ($ET_{o\ mc}$) is influenced by the local microclimate, created by surrounding dry areas, buildings or pavements. The *microclimate coefficient* (K_{mc}) is defined as

$$K_{mc} = \frac{ET_{o\ mc}}{ET_o} \quad (45)$$

and accounts for impacts on ET by exposure to sun (e.g., north oriented versus south oriented areas), external shading by buildings, hot and cool areas, reflected and emitted radiation from structures, wind blockage by buildings and other vegetation, and transfer of sensible heat from low ET surroundings, such as structures and paved areas, that make $ET_{o\ mc}$ depart from the ET_o that is observed in large, well-watered, exposed surfaces.

Values for K_{mc} are listed in Table 12 for general classes of vegetation. The “high” category ($K_{mc} > 1.00$) reflects microclimate conditions that increase evapotranspiration, such as planting in direct sunlight near paved or other non-vegetated surfaces, near reflective or heat-absorbing surfaces such as windows or buildings, or in exposed, windy conditions. The “low” category ($K_{mc} < 1.00$) represents environments where the plantings are shaded, away from dry, hot surfaces and buildings or shielded from wind. The average or medium category ($K_{mc} = 1.00$) represents environments similar to those that characterize reference conditions for ET_o measurement, where buildings, pavements, shading and reflective surfaces do not influence the ET by the landscape (e.g., parks). Values for K_{mc} can be interpolated between the high, average, and low classes and should be selected for each sector of a landscape. It is advisable to perform local measurements to confirm or to derive local K_{mc} values.

Typically, the objective of landscape irrigation is to promote appearance rather than biomass production, unlike agricultural crops. Therefore, irrigation of landscapes is normally managed in order to apply less water than what is needed for full ET_v , thus reducing ET and introducing an intentional water stress factor, K_{sm} :

$$K_{sm} = \frac{ET}{ET_v} \quad (46)$$

where ET is actual evapotranspiration by the vegetated surface and $K_{sm} < 1$. The magnitude of the stress factor depends on the physiological requirements and morphological characteristics of the plants and the desired or minimum acceptable appearance (Table 13).

Table 13 helps making the distinction between water needs and stress tolerance. While all types of turfgrass have the same water needs, as noted by the same K_v (Table 11), given their similarity in height and structure, stress tolerance of cool season turfgrass is lower than that of warm season turfgrass. As a consequence, the latter can be maintained with less irrigation water and is thus recommended in areas with higher ET_o and/or limited water availability.

Computation of K_{sm} can be made according to Eqs. (31) and (32).

Besides savings of water, deficit irrigation can bring savings in mowing or pruning needs due to the reduced growth caused by water stress.

Table 12 Microclimate factor (K_{mc}) for landscape plant types.

Vegetation	K_{cm}		
	High (harsh environment)	Average (reference condition)	Low (protected environment)
Trees	1.4	1.0	0.5
Shrubs	1.3	1.0	0.5
Groundcover, flowers	1.2	1.0	0.5
Mixture of trees, shrubs, and groundcover	1.4	1.0	0.5
Turfgrass	1.2	1.0	0.8

Allen et al. (2020).

Table 13 Managed stress factor (K_{sm}) for landscape plant types and soil water depletion fraction (p) for no transpiration-reducing stress.

Vegetation category	K_{sm}			
	High stress	Average managed stress	Low stress	Depletion fraction (p)
Trees	0.4	0.6	0.8	0.6
Shrubs, desert species	0.3	0.4	0.6	0.6
Shrubs, non-desert species	0.4	0.6	0.8	0.6
Groundcover	0.3	0.5	0.8	0.5
Annuals (flowers)	0.5	0.7	0.8	0.4
Mixture of trees, shrubs, and groundcover	0.4	0.6	0.8	0.6
Cool-season turfgrass	0.7	0.8	0.9	0.4
Warm-season turfgrass	0.6	0.7	0.8	0.5

Allen et al. (2020).

Irrigation water requirements

The soil water balance is calculated for the effective rooting depth as:

$$\theta_i = \theta_{i-1} + \frac{(P_i - RO_i) + I_{wi} - ET_{ci} - DP_i + GW_i}{1000 z_{ri}} \quad (47)$$

where, in addition to the symbols used before, DP_i represents deep percolation [mm], GW_i is groundwater contribution [mm], and z_{ri} is the rooting depth [m], all referred to day i . DP is often estimated as $DP_i = 0$ when $\theta_i \leq \theta_{FC}$ and $DP_i = 1000 (\theta_i - \theta_{FC}) z_{ri}$ otherwise. GW is estimated from soil hydraulic properties and the water table depth. z_{ri} can be predicted assuming a linear variation from planting to maximum rooting. Maximum root depths for most common crops are presented in Tables 3, 4, 7–10.

The latest date for scheduling irrigation to avoid water stress is when $\theta_i = \theta_p$ (Eq. 32). However, irrigation is often scheduled when the “management-allowed depletion,” MAD , is attained. Generally, $MAD < p$ when there is risk aversion or uncertainty, and $MAD > p$ when plant water stress is intentional. Then

$$\theta_i = \theta_{MAD} = (1 - MAD) (\theta_{FC} - \theta_{WP}) + \theta_{WP} \quad (48)$$

In the case of landscapes where deficit irrigation is to be implemented ($K_{sm} < 1.0$), Table 14 can assist in the selection of a target MAD prior to irrigation that produces the desired K_{sm} on average.

The net irrigation depth to be applied will be

$$I_{wi} = 1000 z_{ri} (\theta_{FC} - \theta_i), \quad (49)$$

which summed for the entire season leads to the irrigation water requirement (IWR):

$$IWR = \frac{ET_c - P_e - GW - \Delta S}{1 - LR} \quad (50)$$

where P_e is the effective precipitation (gross precipitation less all runoff and deep percolation), GW is groundwater contribution or capillary rise, ΔS is the change in soil water storage in the root zone between planting and harvesting, and LR is the leaching requirement (the percentage of irrigation water that must pass through the root zone to keep the salinity of the soil below a specified value). The soil water balance is currently computed through crop-water simulation models, which allow the selection of best irrigation scheduling alternatives, e.g., the SIMDualKc model that adopts the dual crop coefficient approach (Rosa et al., 2012).

Table 14 Management allowed depletion (*MAD*) fraction to produce the stated managed stress factor (K_{sm}) given the depletion fraction for no *ET*-reducing stress (p) and assuming complete refilling of the root zone with each irrigation (*MAD* is expressed as a decimal).

Average K_{sm}	$p = 0.3$	$p = 0.4$	$p = 0.5$	$p = 0.6$	$p = 0.7$
1.00	0.30	0.40	0.50	0.60	0.70
0.95	0.47	0.57	0.66	0.75	0.86
0.90	0.55	0.65	0.73	0.81	0.88
0.85	0.62	0.71	0.79	0.86	—
0.80	0.68	0.76	0.83	0.89	—
0.75	0.74	0.80	0.87	—	—
0.70	0.78	0.84	0.89	—	—
0.65	0.82	0.88	—	—	—
0.55	0.90	—	—	—	—
0.50	—	—	—	—	—

—, indicates that the *MAD* value approaches or exceeds 1, so the soil water content approaches or exceeds the permanent wilting point and the vegetation is in danger of dormancy or death.

Pereira and Trout (1999).

The gross irrigation water requirement is computed as

$$GIWR = \frac{IWR}{BWUF} \quad (51)$$

where *BWUF* is the beneficial water use fraction, which includes ET_c and *LR*, and is total water applied. Indicative values of *BWUF* are presented in Table 15.

Limitations

Reliable estimates of crop or landscape water needs are necessary in many situations, such as hydrologic studies, watershed management, and irrigation planning and management. In recent decades, the approach proposed by FAO (Allen et al., 1998) to estimate crop water needs has been consolidated, given the sound physical basis and appropriate parameterization of the Penman-Monteith equation for the calculation of the reference evapotranspiration, together with the availability of tabulated, transferable values of single time averaged or dual crop coefficients for a wide variety of crops.

Despite the robustness of the method, there are still many situations where it is not properly used. A common error is using other equations rather than the $PM-ET_o$ equation to calculate reference evapotranspiration. This obviously leads to or requires different crop coefficients from the correspondent tabulated values, when conducting studies to determine crop coefficients or calculate crop water needs. Studies using a different ET equation should therefore consider the ratio between ET_o equations to allow the conversion of the derived K_c values using those equations or to be able to use the tabulated K_c values that refer to the PM reference ET_o .

FAO 56 introduced the distinction between actual and standard crop coefficients, with the latter referring to crops cultivated in pristine conditions. However, cultivation practices are often far from pristine due to water stress, salinity stress or stresses produced by various insufficiencies of agronomic nature, which are often not recognized or even accepted by many researchers or users, and lead to an incorrect use of the tabulated K_c values.

Conclusions

The population increase and the current politics towards a “greener” agricultural sector demands greater food production on less farmed land. In addition, the climate change challenges, in particular the decrease in water availability and increased competition with other users, enhances the importance of minimizing water use in agriculture and promoting irrigation water savings while maintaining or increasing crop production. This may be attained with an adequate irrigation scheduling and adoption of irrigation systems with higher efficiency (Pereira et al., 2009).

Further research is required regarding the relationships between soil evaporation, transpiration, fraction of soil wetted or fraction of ground covered by the crop, namely in fruit crops and other partial-cover crops. The impacts of mulches on K_c and K_{cb} values constitute another area where further needs of research have been identified. Finally, more research is welcomed on real-time irrigation decision support systems with particular focus on the use of soil water balance models that allow the integration of information based on remote sensing and sensors data.

Abstract

Water harvesting is the intentional collection and concentration of rainwater and runoff to offset irrigation demands. Secondary benefits include decreased flood and erosion risk. Water harvesting techniques include micro- and macro-catchment systems, floodwater harvesting, and rooftop and groundwater harvesting. The techniques vary with catchment type and size, and the method of water storage. Micro-catchment water harvesting, for example, requires the development of small structures and targets increased water delivery and storage to the root zone whereas macro-catchment systems collect runoff water from large areas. The sustainability of water harvesting techniques at the local level are usually constrained by several factors such as labor, construction costs, loss of productive land, and maintenance, suggesting that multiple solutions are required to sustain the benefits of water harvesting techniques.

Key points

- Water harvesting is important in rainfed agroecosystems to offset moisture deficit, particularly in semiarid environments.
- Water harvesting can also decrease run-off on slopes and help mitigate flood risk.
- Water harvesting represents a good example of sustainable management of water resources that contribute to water and food security.
- Water harvesting involves diverse methods of collecting and managing floodwaters and surface runoff.
- About 3 million small reservoirs are in operation in semi-arid regions, supporting 15% of the world population.
- Water harvesting focuses on the efficient use of available water.
- Water harvesting technologies reduce complete crop failure by 7–20%.
- Water harvesting technologies can bridge up to 40% of the yield gap of attributable to water deficit.
- Both socio-economic and biophysical drivers constrain water harvesting.
- Multiple solutions are required to implement and sustain water harvesting techniques.

Definition

Water harvesting has been defined and classified in several ways. A general definition of water harvesting is the process of concentrating precipitation through runoff and storing it for beneficial use (Oweis et al., 2012). However, a broader definition is the collection and concentration of rainwater and runoff and its productive use for irrigation of annual crops, pastures, and trees, for domestic and livestock consumption and for ground water recharge (Prinz, 2011). Although there are slight variations in definitions, the term ‘water harvesting’ generally refers to the collection of rainstorm-generated runoff from an area (a catchment) to provide water for human, animal, or crop use. A secondary benefit of water harvesting on slopes is decreased runoff induced erosion. The water thus collected can either be utilized immediately, as for irrigation, or be stored in aboveground ponds or in subsurface reservoirs, such as cisterns or shallow aquifers, for subsequent utilization. As such, water harvesting is an ancient practice that has enabled some societies to survive in semiarid and arid areas where other sources of fresh water (e.g., rivers, lakes, or aquifers) are scant or unavailable.

Introduction

Water scarcity and quality issues caused by climate change and human actions are increasingly threatening food security and nutrition through their impacts on food systems (Young et al., 2021). This mainly presents a higher risk to the livelihoods of rural people by reducing crop and livestock yields (Payus et al., 2020). The FAO's State of Food and Agriculture report (FAO, 2020) indicated that 3.2 billion people live in agricultural areas with high to very high-water shortages or scarcity, of whom 1.2 billion people—roughly one-sixth of the world's population—live in severely water-constrained agricultural areas. This same report further elaborated that water scarcity is a particularly serious issue in Northern Africa and Western Asia, where per capita freshwater has declined by more than 30% and where the average annual volume of water per person barely reaches 1000 m³, which is conventionally considered the threshold for severe water scarcity. In terms of agricultural land affected, 128 million hectares of rainfed cropland (11%) and 656 million hectares of pastureland (14%) face frequent droughts, while 171 million hectares of irrigated cropland (60%) are subject to high or very high-water stress.

Either a change in demand and user practices, or alternate water resources, are required to sustain the agricultural sector. In this line, improved water management strategies, which includes a range of options is a crucial component to reduce water risks and attain potential yields in agriculture for improved food security and nutrition (FAO, 2020). The inherent challenges are to manage and adapt to weather variability, and to use water from rainfall more productively. According to Duveskog et al. (2003), there are two broad strategies for increasing yields in rainfed agriculture: (a) collecting or harvesting more water and infiltrating it into the root-zone; and (b) conserving water by reducing root-zone evaporation and drainage losses.

Water harvesting technology is especially relevant to the semi-arid and arid areas where the problems of environmental degradation, drought and population pressures are most evident (Piemontese et al., 2020). It is an important component of the package of remedies for these problem zones, and interest in water harvesting has been renewed in recent decades due to the growing demand for water for agriculture and urban development caused by higher population pressure and climate change. This interest has also led to increases in the understanding, implementation and management of water harvesting systems (Oweis et al., 2012). Other applications of water harvesting include the collection of run-off water to mitigate erosion (LaFevor and Ramos-Scharron, 2021) or flood risk (Ward et al., 2021). This chapter presents the history; principles, concepts, and components of water harvesting; the relationship between water harvesting and the hydrological processes including soil erosion and flood prevention; categories of water harvesting; and benefits and constraints of water harvesting.

History of water harvesting

Water harvesting has been employed for thousands of years for multiple purposes (Hofman-Caris et al., 2019). The art of inducing, collecting, and utilizing runoff has been practiced by desert-dwelling communities since antiquity, across disparate regions covering southwestern Asia, northern Africa, and southwestern and North America. Remnants of extensive water-harvesting systems are found in these regions. One frequently referenced example from the ancient world is the works of the ancient Nabateans, who inhabited the Negev Desert of southern Israel some 2000 years ago. To sustain their population in the desert environment, the Nabateans built extensive terraces and channels, and hewed out numerous cisterns. The Nabateans were also skilled at choosing appropriate sites for their cisterns and at ensuring that they could be filled with water annually by harnessing rainfall and runoff.

Historically there were two types of water-harvesting techniques, referred to as runoff farming and water spreading. Both techniques enable farming in desert areas of annual and perennial crops. Runoff farming is defined as the application of water-harvesting techniques to enable farming in desert areas (that is to say, collecting runoff from sloping areas and using it to irrigate plots or tracts of flat land, where crops could be grown). In ancient times, stone dikes were constructed across tributary streambeds, thus forming a series of terraced fields. These fields were watered by flows arriving from the upper watershed of the stream, as well as from the adjacent hillslopes. The slopes were often divided into sections, the runoff from each of which was led by means of constructed channels to specific fields (Fig. 1). The water retained and infiltrated in each field was then utilized by annual crops (e.g., wheat or barley) or by perennial crops (e.g., grapevines, olive trees, or other fruit trees).

Water spreading, another form of water harvesting, consists of diverting flash floods from intermittent streams (known as wadis in the Middle East, arroyos in the American Southwest, and dongas in parts of Africa) on to adjacent tracts of land. It is a simple form of flood irrigation, controlled by dikes, check dams, or channels designed to direct and spread the expected flow. It is generally used to irrigate pastures and rangelands, but in places also to sustain groves of trees in arid areas. Water spreading is typically practiced on small watersheds of a few square kilometers. The approach does not work well in larger watersheds because extreme rainfall may pool to such an extent that simple diversion structures are breached. More complex systems can alleviate this risk, such as the construction of dams designed not to retain the floods but merely to detain and regulate them. Farm units located downstream from the dam then get supplied with controlled flows of water. Such dams, called 'detention dams,' are built across a stream to temporarily impound the flood. A large-diameter open pipe and/or leaky barriers is laid through the dam to permit downstream flow at a predetermined rate, as through the drain of a bathtub. Thus, a flash flood that would normally last just a few hours is made to flow through the pipe and on to a series of fields for perhaps several days. The field dikes (made of compacted earth or stone) can then be built economically and safely to withstand floods of a known maximal intensity, so farming operations can be planned accordingly (Fig. 2).

A growing awareness of the potential of water harvesting for improved crop production and sustainable intensification of agriculture arose in the 1970s and 1980s (Piemontese et al., 2020). Water harvesting has been widely applied in different

Fig. 1 Ancient runoff farming in the Negev: water trickling off barren slopes was directed to terraced fields in the wadi bed.

socio-ecological contexts with hotspots in large portions of East Africa and Southeast Asia (Piemontese et al., 2020; Fig. 3). Following such development, several water harvesting technologies have been set up in different regions of the world since the 1980s to restore degraded landscapes, conserve soil and water and improve agricultural productivity. For example, globally, about 3 million small reservoirs are in operation in semi-arid regions, supporting 15% of the world's population in semi-arid regions (Mady et al., 2020).

Principles, concepts and components

The basic principles of water harvesting are related to crop-water relationships and are focused on the efficient use of available water (Duveskog et al., 2003). They are about capturing precipitation falling in one area to increase the amount of water available for crop production and decrease runoff risk (Mekdaschi and Liniger, 2013). The principles are summarized in Table 1.

The basic principles of water harvesting summarized in Table 1 indicate that water harvesting is part of sustainable land management or integrated water resource management strategies (Mekdaschi and Liniger, 2013). The principles cover diverse water management strategies including the management of excess water from rainfall and seasonal flooding; increasing rainwater capture and availability, making use of surface runoff; improving direct water infiltration and reducing evaporation; soil water conservation practices that prevent surface runoff and keep rainwater in place; and increasing water use efficiency. Such coverage of diverse water management strategies suggest that a combination of strategies is required to improve the productivity of water.

For the water collection systems to be successful, the main determining factors are the water source, the type of water lifting or pumping system, and the water application mechanisms. Water sources are mainly rainwater and runoff, but harvested water may refill the other water sources such as river/lakes, ponds/springs, and shallow groundwater for later use. As a result, water harvesting usually has four basic components: catchment or collection area, conveyance system, storage component and application area or target (Mekdaschi and Liniger, 2013). The components could be adjacent to each other or connected by a conveyance system or in some cases the storage and application areas may also be the same, typically where water is concentrated in the soil for direct use by plants (Fig. 4).

Water harvesting and hydrological processes

The hydrological cycle of the earth is the sum of all processes in which water moves from the land and ocean surface to the atmosphere and back in the form of precipitation. Of the many processes involved in the water cycle, rainfall and runoff are the most important process related to water harvesting. Whenever the rate at which rainwater is applied to the soil surface exceeds the rate of infiltration into the soil, the excess tends to accumulate over the surface. Where the surface is not perfectly flat and smooth, the excess

Fig. 2 Two general methods of water spreading by diversion from an intermittent stream (a wadi) on to adjacent land: (a) diversion of an uncontrolled flow over unlevelled land by means of a zigzag series of earthen dikes; and (b) diversion of a controlled flow from a detention dam to a series of level basins with concrete- or stone-lined spillways.

water collects in depressions, forming puddles. The total volume of water thus held, per unit area, is called ‘surface-storage capacity.’ It depends on the geometric irregularities (roughness) of the surface as well as on the overall slope of the land. Only when the surface storage is filled, and the puddles begin to overflow can actual runoff begin. The term ‘surface runoff’ thus represents the portion of the water supply to the surface that is neither absorbed by the soil nor accumulates on its surface, but that runs downslope.

Surface runoff typically begins as sheet flow but, as it accelerates and gains in erosive power, it eventually scours the soil surface to create channels causing soil erosion. Water harvesting technologies have the potential to reduce the peak discharge and heavy rainfall to cause soil erosion, as the systems were designed by diverting the precipitation runoff to the area where it can be used or stored (Kim et al., 2021). One of the primary benefits of water harvesting technologies at field level is to reduce soil erosion and to improve rainfall infiltration and conservation in the soil profile (Bossio et al., 2007). In this line, studies reported the benefit of water harvesting technologies such as tied ridges, mulching, conservation tillage, and furrow systems in improving on-site water availability for plant growth and reducing runoff and soil erosion from agricultural fields (e.g., Tolossa et al., 2020). Water harvesting technologies can also improve soil-moisture content in the soil layer due to increased infiltration of ponded water (e.g., Araya and Stroosnijder, 2010).

Also, hydrological processes at catchment scale are controlled by many physical and climatic factors. Hydrological processes such as runoff, infiltration, groundwater recharge, etc. are also likely to change following the treatment of catchments with different water harvesting technologies (Garg et al., 2021). Several studies conducted across the world demonstrated significant reductions in

Fig. 3 (a) Global map of archetypes of successful water harvesting, and regional snapshots in (b) East Africa and (c) South-Eastern Asia. When multiple overlapping archetypes, the archetype with the smallest spatial extent is shown. From Piemontese L, Castelli G, Fetzer I, Barron J, Liniger H, Harari N, Bresci E and Jaramillo F (2020) Estimating the global potential of water harvesting from successful case studies. *Global Environmental Change* **63**: 102121.

runoff and sediment yield at the catchment outlets after the construction of diverse water harvesting technologies such as earth bunds with trenches, stone bunds, and check-dams (e.g., Dagnew et al., 2017; Garg et al., 2021). For example, a study conducted in South Asia demonstrated a reduction in surface runoff and soil erosion by more than 60% and 75%, respectively following the implementation of water harvesting technologies (Garg et al., 2021). A study in Ethiopia showed that soil bunds with 50-cm-deep furrows resulted in a reduction of sediment loss by half compared to untreated catchments (Dagnew et al., 2017). Similarly, a study in Southeast Asia demonstrated that water harvesting technologies are efficient in reducing runoff and total sediment yield at the catchment scale.

Categories of water harvesting

Catchment type and size, and the method of water storage are the two most frequently used criteria to classify water harvesting systems. Based on these criteria, five groups of water harvesting systems are identified: (i) micro-catchment systems, (ii) external/macro-catchment systems, (iii) floodwater harvesting, (iv) rooftop/courtyard harvesting and (v) groundwater harvesting.

Table 1 Principles of water harvesting.

Principles	Description
Use rainwater effectively.	Addresses uneven and erratic rainfall conditions through implementing storage techniques to increase the availability of water for crops.
Make effective use of soil water reserves.	Effective use of stored water in the soil profile through crop choice and tillage.
Take measures to avoid runoff.	Physical soil and water conservation and agronomic measures to reduce generation of runoff and soil erosion.
Avoid wasting water through evaporation.	Agronomic measures to reduce water that evaporates directly from bare soil, including the use of modern irrigation practices and controlled timing of water application.
Reduce water losses through drainage.	The combination of agronomic, agroforestry and soil-based measures that increase ground cover, improve soil structure and soil water holding capacity.
Planned irrigation	The use of appropriate irrigation methods, time of application and consideration of crop-water requirements.

Fig. 4 Basic components of two water harvesting systems: (a) catchment area, storage and application area are clearly separated and connected by conveyance systems; (b) catchment area is bordering application area. Storage is in the soil or ground below the application area. Image Credit Mekdaschi SR and Liniger H (2013) *Water Harvesting: Guidelines to Good Practice*. Centre for Development and Environment (CDE): Bern; Rainwater Harvesting Implementation Network (RAIN): Amsterdam; MetaMeta: Wageningen; The International Fund for Agricultural Development (IFAD): Rome.

Micro-catchment systems

Micro-catchment water harvesting requires development of small structures across mild land slopes, and is designed to trap and collect runoff from a relatively small catchment area (10–500 m²) to support the growth of plants (Fig. 5; Ali et al., 2010; Mekdaschi and Liniger, 2013; Reddy, 2016). This system targets increased water delivery and storage to the root zone, with application to the growth of arable and fodder crops, shrubs, or trees, with added benefits of groundwater recharge. Water availability to plants depends on the micro-catchment runoff yield and water storage capacity of both the plant basin and the soil profile in the plant root zone (Ali et al., 2010). The ratio between the catchment (collection) area to the cultivated (application) area can vary between 2:1 and 10:1 (Mekdaschi and Liniger, 2013). The size of the catchment can be easily controlled by the farmer, which makes the system easy to adapt and replicate.

Micro-catchment water harvesting has the greatest impact in semi-arid to arid areas with high rainfall variability within seasons but works in many environments. Almost any slope can accommodate micro-catchments, including nearly level plains. Soils need

Fig. 5 Micro-catchment water harvesting system. Image credit Reddy PP (2016) Micro-catchment rainwater harvesting. In: *Sustainable Intensification of Crop Production*. Springer: Singapore.

to be deep enough to construct holes or pits that store the collected water. Soils susceptible to sealing and crusting are particularly suitable for inducing runoff in the catchment area. Furthermore, micro-catchment water harvesting can be applied on highly degraded soils where it can be used in the productive rehabilitation process, reducing erosion and flooding. A few examples of technologies that can be categorized under micro-catchment water harvesting systems are summarized in Table 2.

Table 2 Examples of micro-catchment water harvesting technologies (African Development Bank, 2009).

Technologies	Description
Planting pits	Planting pits are used as a water harvesting method to prevent water runoff and erosion and increase infiltration. Pits are dug 20–30 cm wide and 20–30 cm deep and are designed to capture water to plant few seeds of annual or perennial crops. Pits are often found in combination with stone bunds to rehabilitate degraded and crusted lands, and to bring them back into productive land. Planting pits are applied on flat to gently sloped terrain (0–5%) that receives annual rainfall of 350–600 mm. This form of micro-catchment is best suited for land with low permeability, such as silt and clay soils. To further increase crop production, organic matter (such as compost or manure) can be placed in the pits as fertilizer. Many different names are used for planting pits, such as Zai (Zay), Chololo, Mantengo, Ngoro and Tassa. They are widely applied in Sahelian countries, such as Mali, Burkina Faso, and in the Yatanga and Niger regions.
Micro-basins	A micro-basin is a small structure with the shape of a half or a full circle, excavated to obtain a small basin for planting a tree. Micro-basins vary in size; they are small in moist agroecological zones (e.g. 1-m diameter) and large in dry ones (e.g. 2 m). Micro-basins must be carefully lined out on the slope with intermittent placements for runoff control and proper spacing. The procedures in implementing a micro-basin includes cutting of soil as per site requirement, excavating the earth work in a half moon shape throughout its required length and filling the excavated earth in the upper slope for cultivation. After tree planting, micro-basins require little maintenance but weed control may be needed.
Permanent vegetative barriers and strips	Permanent vegetative barriers and strips are made of grasses, shrubs, or trees (often combined) to reduce soil loss and increase infiltration. They are mainly used to replace physical structures on soil with good infiltration (sandy, silty) found on gentle slopes. They are suitable for slopes with gradients of less than 15%. The width of grass strips ranges from 0.5 m to 1.5 m. On steep slopes the width ranges from 2 m to 4 m. Trees and shrub strips are generally wider up to 5–10 m. Since vegetative strips are usually laid along the contours, the distance between them is dictated by the slope of the land. On gentle sloping land, the strips are spaced at 20–30 m, while on steep land the spacing may be 10–15 m. This practice works well in small-scale as well as in large-scale systems. Vegetative strips can also provide firewood and fodder for livestock if palatable varieties of grass or densely spaced bushes are used (cut and carry). They are the least costly or labor demanding type of cross-slope barriers. They are a popular and easy way to ultimately “terrace” land, especially in sub-humid areas, as over time soil eroded upslope is trapped by the vegetation.
Tied earth ridges	Small earth ridges, with furrows between them, blocked with earth ties every 0.5–1.0 m are termed tied ridges. On gentle slopes typical dimensions of the ridges are 20–25 cm height and 0.5–1.5 m spacing between ridges depending on rainfall and the crop to be grown. On flat land compacted bunds and ridges are constructed to generate runoff with a spacing of 1.2–10 m and a ridge height of 30–100 cm, depending on rainfall, crop to be grown and soil characteristics. Runoff is collected between the ridges. The catchment to application area ratio ranges from 1:1 to 5:1. This type of ridge needs maintenance every cropping season and has to be rebuilt about every 5–6 seasons. Tied ridges are often considered an in situ form of water conservation, though where the ridges are large it can be argued that they act themselves as a form of micro-catchment.
Contour earth bunds	WOCAT database on sustainable land management (SLM) measures indicates that Bunds and Fanya Juu are techniques used in agriculture to collect surface run-off, increase water infiltration, and prevent soil erosion. They are suitable for slopes with gradients ranges from 3% to 50%. To avoid lateral water flow and breaching of the bunds cross ties are constructed at regular intervals. Such bunding systems are used in areas with 300–600 mm annual rainfall. They can be applied on all types of relatively permeable soils (e.g., alluvial, red, laterite, brown and, shallow and medium black soils). While this system is often used for the cultivation of annual crops such as maize (<i>Zea mays</i>), tef (<i>Eragrostis tef</i>) or beans (<i>Vicia faba</i> L.), more water-demanding crops, such as bananas, fruits and vegetables may be planted where runoff concentrates immediately above (and sometimes just below) the bund. Contour bunds may be used specifically as a water harvesting technology for tree establishment.

External/Macro-catchment system

Macro-catchment/external catchment systems collect runoff water collection from large areas far from where it is being used (Fig. 6; Mekdaschi and Liniger, 2013). The water may generate from roads, hillsides, and pastures. Several technologies are categorized under this water harvesting system (Table 3), usually designed to control large runoff flows (Kimani et al., 2015). The catchment size ranges from 200 ha to 50 km² and the catchment area cropping area ratio of macro-catchment water harvesting system ranges from 100:1 to 10,000:1 (Kimani et al., 2015).

Macro-catchment water harvesting systems are more applicable in arid and semi-arid areas where the amount of rainfall during the dry season not enough to meet the crop demand. Agricultural production is not possible without irrigation, and in some instances, there is not enough water for household consumption and livestock. The most common sources of runoff water for this system include runoff generated on steep slopes and uncultivated land.

Fig. 6 An example of a macro-catchment water harvesting system linked to a pumping and small-scale irrigation system. Table 3 Most common macro-catchment water harvesting techniques (Kimani et al., 2015; Gebreyess and Amare, 2019).

Technologies	Description
Small earthen Reservoirs	These are earthen structures which are useful to store the runoff water that comes from upstream catchment areas. They are important water harvesting structures that store water for human consumption, crops, and animals. In most cases, the stored water is not free of debris and sediments.
Sand Dams	Simple, easy to maintain and reproducible water harvesting techniques that collect and store clean water for homestead consumption and irrigation. This structure is usually constructed along riverbeds and is used to store water in the sand, prevent run-off, conserve soil, and increase the soil moisture content for crop production. Water from the sand dams can be extracted through holes, or through a pipe that conveys to a tank or a shallow well and the water can be used for multiple purposes. Protecting the sand dams from evaporation prolongs use.
Cistern and Water Tanks	Underground storage tanks that collect water from bare lands, cultivated hillslopes or road catchments during the rainy season. To avoid regular cleaning, small sediment settling basins are connected at the inlet of the tank. The cisterns have plastered walls and lined surfaces. Cisterns are more appropriate in areas where the evaporation is high, skilled labor is available, water scarcity is high, and quality of water is required.
Ponds	Small structures that can store up to 20,000 m ³ of water and have less than 5 m depth below the top-soil surface (Fig. 7). Storage capacity of commonly constructed ponds ranges from 30 m ³ to 50 m ³ . Open ponds are suitable in areas where unskilled labor is available, the evaporation loss is low, efficient water conveyance and applications are used, and when the capital investment is limited. However, they are not suitable in areas where there is a land shortage or where ponds risk malaria disease. The water collected with ponds can be used for livestock and irrigation purposes. Evaporation losses, leaching and sedimentation are the most important factors affecting the sustainability of ponds. In addition, the lack of access to simple water-lifting technologies and watering cans constrains the effective use of water stored in ponds for multiple purposes. Further, lack of fencing and protection of ponds can lead to water pollution. Cultivated hillslopes, natural watercourses, and footpaths are the major water sources for constructed ponds. Water loss due to evaporation and seepage can be decreased in open ponds with shade and lining with clay, plastic and cement as needed (Fig. 8).
Recharge well	Serve to increase water flow to deep aquifers. This method is often applied to recharge deep aquifers where application of water to the land surface are not effective at recharging these aquifers. Also, this technique is more practical in arid and semi-arid areas where drip irrigation is common. The technique is common across the globe and practiced widely in Africa, Southeast Asia, and United States of America.

Floodwater harvesting

Floodwater harvesting is defined as a collection of stream flows for use in irrigation and flood prevention. Streambed (refers to as floodwater harvesting) within streams (wadi) beds and floodwater diversion (refers to as off wadi harvesting) are the two types of floodwater harvesting systems (Oweis et al., 2012). Streambed floodwater harvesting involves building structures across wadi beds to partially or completely dam floodwater and to store it either in surface reservoirs or in channel sediments (Fig. 9). A widespread type of this techniques called terraced wadi system, which are commonly built for agricultural purposes. Terraced wadi systems consist of a series of small dams (check dams) that intersect parts of a wadi course. The check dams lower the runoff velocity of the floods and thereby their transport capacity. This in turn leads to the accumulation of sediments behind the dams and gradually build a terrace or sediment reservoir upstream that might be cultivated (Beckers et al., 2013). Other types of this technique are groundwater dams such as sand storage dams and subsurface dams. Sand storage dams’ function with the same principle as the

Fig. 9 Examples of floodwater harvesting techniques. Slopes are exaggerated (Beckers et al., 2013). From Beckers B, Berking J and Schütt B (2013) Ancient water harvesting methods in the drylands of the Mediterranean and Western Asia. *Journal for Ancient Studies* 2: 145–164.

terraced wadi system. Subsurface dams are built into the alluvial fill of streams by excavating a trench down to an impervious layer and building a wall in the trench which is subsequently backfilled with the excavated material (Beckers et al., 2013).

Floodwater diversion systems are built to deflect floods from a stream (wadi) channel to convey the water to adjacent storage devices or fields (Fig. 9). This is either accomplished by damming parts of the wadi or blocking the entire channel. The retaining structures are called diversion dams. Floodwater diversion system usually categorized as: (i) spate diversion where flash floods are diverted from ephemeral rivers, (ii) inundation canals that starts to flow when the flow reaches at a certain level, and (iii) recession irrigation where perennial river overtops to its banks.

Floodwater harvesting is most suitable in arid and semi-arid environments where there is high variability of rainfall and water shortages (Ghahari et al., 2014). However, floodwater harvesting is also used in temperate climate for flood prevention. This technique is widely used in North and East Africa, Italy, Israel, Jordan, Tunisia, Libya and Spain for agricultural purpose, and in the Netherlands and Scotland mainly for flood prevention (Alcoforado, 2018). Spate irrigation, for example, is one of the forms of floodwater harvesting used widely in Eastern Africa (Gebreyess and Amare, 2019). Spate irrigation helps to harvest and reuse runoff water and sediments, produce virtual water and recharge groundwater (Ghahari et al., 2014). Direct runoff farming technique is used for immediate use of water in the agriculture areas such as bed preparation, and to make for ridge preparations especially to for the upcoming runoff and floodwater. The water can be collected from roads, hillsides, soil ridges, and short-lived streams. This water is used for growing cereal crops (wheat, barley, maize), vegetables (onion, cabbage, garlic, tomato, etc. and fruit trees).

Rooftop harvesting

Rooftop water harvesting is a system of water harvesting from roofs and paved courtyards during the rainy season (Fig. 10). The harvested water is mainly used for domestic purposes, very rarely for garden crops, too. Rooftop water harvesting yields good quality of water and hence, it is the most common water harvesting system around homestead and schools.

This water harvesting technique is applicable for farmers who would like to harvest water using ponds and tanks for later use during the peak dry season where water shortage affects the community. Rooftop catchments are other options preferred and feasible for farmers (Tadesse et al., 2008). Rooftop area and average rainfall in an area determines the total quantity of water that can be collected or harvested. This is small compared to other forms of water harvesting, but large volumes of water can still be collected. For example, using rooftop water harvesting just on 19 buildings at South Indian University could collect about 114000 m³ of water to help resolve scarcity in the non-monsoon season (Anchan and Prasad, 2021). A study of rooftop rainwater harvesting on the slopes of Mt. Elgon, Uganda estimated 163,063 m³year⁻¹ of captured water, giving the potential to save 4–7% of the annual

Fig. 10 Rooftop water harvesting. Image credit Anchan SS and Prasad HS (2021) Feasibility of roof top rainwater harvesting potential-A case study of South Indian University. *Cleaner Engineering and Technology* 4: 100206.

household water demand (Bernard and Joyfred, 2020). Most of the water collected from the rooftop is used for drinking, domestic and livestock consumption.

Rooftop water harvesting can be considered as a technique that helps to harvest rainwater. Various systems or mechanisms can be used to collect rainwater harvested from rooftops. For example, underground water holding tanks, ferrocement jar, polyethylene laminated earth holding tank and concrete tanks can be used to store water harvested from rooftop (Fig. 11). The stored water can be used for drinking, washing, irrigation and livestock (Gebreyess and Amare, 2019).

Groundwater harvesting

Groundwater harvesting involves extracting water from qanats, underground dams and wells (Fig. 12). Qanat systems consists of a horizontal tunnel that taps underground water in deposited fans, which brings it to the surface without using pumps or any other pressurized systems. These systems have an inclination of 1–2%, classified by length as short, medium, and long size qanats and

Fig. 11 Rooftop water harvesting using water tanks in Oromia region, Ethiopia.

Fig. 12 Shallow wells and recharging methods in Amhara region, Ethiopia.

reaching 30 km long (Prinz and Singh, 2000). Underground dams store water below the ground, often using sediment (sand dams) to reduce water loss due to evaporation. These systems filter water so help to minimize water pollution (Prinz and Singh, 2000).

The water harvested through this system can be delivered to the fields steadily and used for agricultural production and homestead consumption (Prinz and Singh, 2000). Ponds, large sized water tanks and ground water dams are needed to extract water from the ground and store for later use while there is a water shortage during the dry season or to supplement when there is not sufficient rainfall.

Groundwater harvesting systems are suitable in areas where the annual rainfall ranges from 500 to 1400 mm (Tadesse et al., 2008). They are also suitable in areas where the evaporation is high, skilled labor is available, water scarcity is high, and good water quality is required (Lulseged et al., 2011). If a farmer uses wells as a water source and ponds for collection of water for irrigation, they could grow crops two times per year and meet the household consumption needs.

Environmental and socio-economic benefits of water harvesting and limitations

Water harvesting is used globally for both socio-economic and environmental reasons (Díaz-Pereira et al., 2016). Socio-economic benefits of water harvesting include increased crop yield and farm income leading to improved food security, decreased soil erosion and conservation, and better social networks. As part of broader strategies to improve agricultural sustainability, water harvesting can have added impacts. For example, a study in Zimbabwe demonstrated that the combined use of inorganic fertilizers and water harvesting technologies helps to close yield gap (Kahinda et al., 2007). Supplemental irrigation due to the use of water harvesting technologies reduced the risks of complete crop failure from 20% down to 7% on average and also enhances transpiration water productivity from 1.75 kg m^{-3} up to 2.3 kg m^{-3} on average, by mitigating intra-seasonal dry spells (Kahinda et al., 2007). A study in the semiarid loess region of China reported water harvesting technologies led to a 10–20% increase in crop yield by enabling supplemental irrigation during critical growth stages (Li, 2003). A regional study in Africa by Lebel et al. (2015) indicated that water harvesting can bridge the yield gaps of maize due to water deficit by 40% of the yield gap under the current condition and 31% under future (2050s) climatic conditions, hence providing an alternative to irrigation from scarce or inaccessible groundwater resources. A study in Ethiopia demonstrated that adoption of rainwater harvesting technology had increased adopters' annual farm income by 35% and daily calorie intake per adult equivalent by 16% compared to the annual farm income of non-adopters

(Mekuria et al., 2020). The cited case studies indicate that water harvesting technologies can have considerable contributions to achieve food security and improve the livelihoods of local communities.

In addition to food and feed production (direct benefits), water harvesting technologies have substantial environmental and social returns, such as combating land degradation and migration from rural to urban areas and employment (Oweis and Hachum, 2009; Díaz-Pereira et al., 2016). In the Southern part of the West Bank, water harvesting technologies such as stone terraces and semi-circle bunds were found to reduce the amount of total runoff by 73–80%, depending on climatic conditions (Al-Seekh and Mohammad, 2009). This cause soil moisture content to significantly increase under these water harvesting techniques compared to the control. A study in Southern Ethiopia indicated that water harvesting technologies such as trenches increased tree biomass (on average by 7.7–25.5 kg/tree), which have positive implications to improving regulating ecosystem services (Alem et al., 2020).

Water harvesting systems can provide many advantages over other irrigation schemes. For example, micro-catchment water harvesting systems are simple and inexpensive to construct and can be built rapidly using local materials and manpower. The runoff water has a low salt content and because it does not have to be transported or pumped, it is relatively inexpensive. Micro-catchments enhance leaching and often reduce soil salinity. An example is the use of micro-catchment techniques in Arizona that have returned land retired from agriculture due to high salt content from groundwater irrigation to productive use (Fidelibus and Bainbridge, 1995). Water harvesting systems, particularly micro-catchment water harvesting techniques have higher runoff collection efficiency and negligible conveyance losses. Water harvesting techniques contribute positively to achieving resilient environment and community through adapting climate change and improving food security.

Despite their many perceived potential benefits, the main constraints regarding the adoption of water harvesting techniques at local level include availability of active farm labor, implementation and maintenance costs, the loss of productive land, equitable access to runoff and related resources, changes of the runoff conveyance channels due to erosion and deposition, extension service and training, level of monthly income, main source of livelihood, and land tenure (Mangisoni et al., 2019). Related studies have shown that land size, access to financial services, access to information and contact with extension officers are some of the variables that have a significantly positive effect on the adoption of in field rainwater harvesting technology, while hired labor has significantly negative correlation with adoption (Badisa, 2011).

Table 4 summarizes the required earthworks or stoneworks for various water harvesting systems. The labor costs for constructing the water harvesting systems are expressed in person days. In general, larger structures (e.g., trapezoidal bunds) may take 50% more labor per unit volume of earthworks than smaller structures (e.g., Negarim micro-catchments) because of increased earthmoving required. Typical rates for earthwork range from 1.0 to 3.0 m³ person/day whereas typical rates for stonework is 0.5 m³ person/day.

The limitations or constraints highlights the need for multiple solutions including incentives for implementation for most effective water harvesting techniques adapted to local environmental and socioeconomic conditions. Also, the planning and implementation of water harvesting techniques should not only deal with hydro-climatic challenges but also looks on the socio-economic challenges for efficient and equitable distributions of resources following the implementation of water harvesting infrastructures. The other important socio-economic reality that should be considered is that the necessary to cooperate in construction as most of the technologies or structures cannot be made by individual farmers.

Conclusion

Water harvesting improves the use of available water from precipitation and run-off by concentrating it for immediate use and storage. The control systems that are implemented can divert water to decrease erosion and flood risk. Under climate change, water harvesting will improve resilience to stresses from droughts and extreme rainfall. Water harvesting can also recharge depleted groundwater sources. Water harvesting involves very diverse methods of collecting and managing floodwaters and surface runoff. Techniques can be grouped as: micro-catchment water harvesting, macro-catchment water harvesting, floodwater harvesting,

rooftop and courtyard water harvesting and groundwater water harvesting. These techniques of water harvesting have diverse socio-economic and environmental benefits including increased crop yield and farm income as well as improved food security, knowledge of soil erosion and conservation and social networks, increased soil moisture content and water availability, reduced soil loss and reduced downstream flooding and siltation, improved infiltration and groundwater recharge, and improved soil fertility. Despite the many potential benefits of water harvesting, the main constraints to implementing at local level include labor, construction costs, loss of productive land, maintenance, equitable access to runoff and related resources, and change of the runoff conveyance channels due to erosion and deposition. The limitations or constraints highlight the need for multiple solutions including incentives for implementation for most effective water harvesting techniques adapted to local environmental and socioeconomic conditions.

Abstract

Irrigation increases yields and ensures the reliability and continuity of crop production. Approximately 40% of the world's food is grown on irrigated land, which accounts for only about 20% of the world's land used for crop production. Various irrigation methods have been developed over time to meet the irrigation needs of certain crops in specific areas. The three main methods of irrigation are surface, sprinkler, and micro-irrigation. In basin, border and furrow—surface irrigation, water flows over the soil by gravity. Sprinkler irrigation applies water to soil by sprinkling or spraying water droplets from fixed or moving systems. Micro-irrigation applies frequent, small water volumes by localized dripping, bubbling, or spraying.

Key points

- Different surface, sprinkler and micro-irrigation methods are described.
- The hydraulic and agronomic features of the different irrigation methods are discussed.
- Their merits and limitations are elucidated in terms of the wetting patterns and water use efficiency.

Introduction

Irrigation is the process of applying water to soil, to meet the water needs of growing plants, and to assist in crops production and in the wellbeing of landscape plants and lawns. The goal is to apply the water to the land as uniformly as possible, so that each plant can take up the amount of water it needs, neither too much nor too little. Water from rivers, reservoirs, lakes, or aquifers is pumped or flows by gravity through pipes, canals, ditches, or even natural streams, and then applied to the irrigated field (Bjorneberg and Sojka, 2005; Brouwer et al., 1988; Hoffman et al., 2007; Israelsen, 1950; Pereira and Trout, 1999; Rohwer et al., 2007). As natural water sources become depleted, the use of recycled, wastewater is growing in prominence. This can create increased challenges, due to soil salinization and the presence of organic compounds or other contaminants that affect the soil and environment.

Applying water to fields and orchards enhances the magnitude, quality, and reliability of crop production—approximately 40% of the world's food is grown on irrigated land, which accounts for only about 20% of the world's land used for crop production. Namely, the areal productivity of irrigated agriculture is almost threefold that of rain-fed agriculture (i.e., that does not use irrigation but instead relies only on direct rainfall).

Various irrigation methods have been developed over time to meet the irrigation needs of certain crops in specific areas. The three main methods of irrigation are surface, sprinkler, and micro-irrigation. In surface (basin, border and furrow) irrigation, water flows over the soil by gravity. Sprinkler irrigation applies water to soil by sprinkling or spraying water droplets from fixed or moving systems. Micro-irrigation applies frequent, small water volumes by dripping, bubbling, or spraying. A fourth, minor, irrigation method is subirrigation, in which the water table is raised to or held near the plant root zone using ditches or subsurface drains to supply the water.

Surface irrigation is thousands of years old. The impact sprinkler, was invented in the US in the 1930s, and quickly found widespread use. Modern drip irrigation with plastic emitters was developed in Israel in the early 1960s. Both sprinkler and drip irrigation offer a practical, usually superior alternative to surface irrigation. Worldwide, about 300 Mha of cropland is equipped for irrigation, out of which about 85% is actually irrigated. This area doubled since 1970, and about 68% of this area is in Asia, 17% in the Americas, 9% in Europe, 5% in Africa and 1% in Oceania. China, India, United States, Pakistan, and Iran account for ca 60% of global irrigated land. About 75% of this land is surface-irrigated, about 18% is sprinkler-irrigated and in about 7% micro-irrigation is practiced. In developed countries sprinkler and micro-irrigation are used on a greater percentage of irrigated cropland, primarily to reduce labor and improve control of water application (ICID: <https://icid-ciid.org/home>).

Several criteria can be used to categorize the irrigation methods. Sprinkler and drip are pressurized irrigation methods in the sense that the water is supplied to the irrigated land at pressures larger than atmospheric via pipes and emitters (sprinklers, sprayers, bubblers drippers). In gravitationally-driven surface irrigation, water is at atmospheric pressure, and the subirrigation water supplied to the root zone is under tension, i.e., at a pressure smaller than atmospheric. Soil water flow dimensionality is another criterion discriminating one-dimensional, vertical, sprinkler, basin (or border) and sub-irrigation from two (or three)-dimensional, vertical and horizontal, soil water flow in furrow and drip (or micro) irrigation. As to the dimensionality of surface streams (waves) flow: for example, in wide basins or in a border strip with cross slope, it is not always that a longitudinal direction dominates, thus the non-negligible transverse flow and variations in water-surface elevation makes these surface flows two-dimensional. A third criterion, related to all irrigation methods, is whether irrigation is supplementary to rainfall as an additional water source, or whether it is full irrigation, whereby crops rarely depend on any contribution from rainfall. Full irrigation is practiced in arid regions experiencing very little rainfall or when crops are grown in semi-arid areas outside of rainy seasons. Supplementary irrigation is used in humid and semi-arid regions when rainfall in the growing season does not meet the full plant water demand. Moreover, in temperate regions, supplementary irrigation is used for high value crops and the production of sensitive root crops, such as potatoes. Erratic weather, associated with climate change, has increased the demand for irrigation across many climatic regions on Earth.

Although manual operation of irrigation systems is still used, most agricultural, residential and landscape irrigation systems, especially the pressurized sprinkler and drip systems, are operated automatically using irrigation controllers and electric solenoid valves. Each irrigation zone has one or more valves that are wired to the controller. When the controller sends power to the valve, the valve opens, allowing water to flow to the lateral lines and water emitters in that zone. This is sometimes triggered via soil moisture sensors installed in the field.

In variable rate irrigation (VRI) practices (within “site-specific” farming), the irrigated fields are delineated to separate management zones (MZ), based on previous-years yield maps and on proxy and remote, soil and plant, sensing, and each MZ is irrigated separately with different irrigation depths. Irrigation depth (or ‘application depth’ in millimeters or inches) is the volume of water applied to a given irrigated area.

Design and management

The design and management of irrigation systems involves agronomic, hydraulic and economic considerations. The irrigation system capacity should meet the crop water demand at critical growth stages and climatological conditions, and also allow for downtime, when the system can be repaired and maintained. The designed system capacity can be decreased by accounting for the use of stored soil water to meet the crop water demand during the peak-use period, and if relevant, also the expected rainfall events during that period. In cases where the water supply cannot match the peak-use rate, water storage in open or closed reservoirs is required (Benami and Ofen, 1984; Cuenca, 1989; Hoffman et al., 2007; Waller and Yitayew, 2016).

Irrigation scheduling refers to the irrigation timing (or frequency) and dosing (daily irrigation depths). The irrigation frequency and the geometry of two or three-dimensional irrigation modes, should account for plant and soil properties such as the depth of root systems and the soil hydraulic conductivity (or capillary length) and water retention characteristic. Crops with shallow root systems planted in coarse-textured, sandy soils should be irrigated more frequently than deep-rooted crops planted in fine-textured, clayey soils. Irrigation dosing is determined mostly by the crop and climatic conditions, varying with the crop growth stages and along the annual seasons. A good understanding of water behavior in the soil-plant-atmosphere continuum (SPAC), of the irrigation system hydraulics, and of the ability to influence them, allows rational decisions, balancing irrigation system, water and other costs with the costs (and benefits) associated with under or over-irrigation (Hoffman et al., 2007).

Irrigation uniformity and efficiency

Irrigation uniformity (IU) quantifies the evenness of water distribution to individual plants, determined mainly by the variation of pressures in a pressurized irrigation system or water surface elevations in a gravity-fed system, responding to and affecting the flow rates at the various locations in the irrigation system.

Non-uniform irrigation means excess water should be applied in certain areas, such that enough water is applied in other areas to minimize plant water stress. The excess water may cause surface runoff and also oxygen deficiency (hypoxia), if the soil profile gets too wet. Several mathematical definitions, which account for the spatial variation of the applied irrigation depths in various irrigation systems, are used to quantify its distribution uniformity (Hoffman et al., 2007).

Irrigation efficiency (IE) can be defined in different scales and contexts. On larger scales it accounts for water losses in reservoirs and during its conveyance to the irrigated fields (conveyance efficiency). At the field scale it accounts primarily for the uniformity of water distribution to its different zones (distribution efficiency) and for operational and accidental spills. Conveyance efficiency and distribution efficiency both refer to the water delivery from the source to a specific outlet emitter. At the soil profile scale, it is usually defined as the ratio between the productive evapotranspiration (ET) water and the total irrigation water that also ends up as runoff and excessive deep percolation losses. Another option is to differentiate between consumptive transpiration (T) water and non-consumptive, irrigation efficiency—reducing evaporation (E) water, although evaporation for cooling and frost protection, as well as deep percolation for salt leaching, are beneficial to the plants (Hoffman et al., 2007).

Surface irrigation

Surface irrigation entails water flowing by gravity over soil. Water is usually supplied by gravity through canals, above or below ground pipes and ditches, with gates, breaches or siphon tubes from the water source to the cropped field. In some locations, however, water may need to be pumped from the source to a field at a higher elevation. Runoff is stopped by a berm, and water ponds behind it; otherwise, flow runs off at the end, and the tailwater can be collected for reuse (Hoffman et al., 2007; Walker and Skogerboe, 1987). If water is reused, surface irrigation efficiencies can be greater than those listed in Table 1. Surface irrigation is also termed ‘controlled flooding’, and its types include furrow (also surge), level basin, and border strip irrigation. Surface irrigation systems are typically used for field crops, pastures, and orchards. A major characteristic of surface irrigation is that the same flow channels conveying water to their distal ends are also the sources of water infiltrating into the soil and being taken up by plant roots. Another distinct characteristic is that the depth of flow is not prescribed, but responds to the difficult-to-characterize hydraulic resistances of the flow channels. Efficiency of surface irrigation systems varies tremendously because of variations in soil type, field uniformity, and management. Surface irrigation is often considered less efficient than sprinkler irrigation or micro-irrigation, because soil, not a pipe, is the water-conveyance system for surface irrigation (Table 1). Nevertheless, a well-managed surface irrigation system on a uniform soil with a runoff-reuse system can approach 90% application efficiency.

The surface irrigation process is comprised of four phases, starting with an advance phase in which the surface water stream propagates over the field from the upper point of entry to the bottom of the irrigated section. Next, during the soaking phase, inflow continues until a sufficient, pre-planned irrigation water depth has been introduced. After cutting off the water inflow, in the depletion phase, the depth of the surface stream is reduced while infiltration, and possibly runoff, also continue. At some stage, the soil surface below the stream is exposed and the recession phase begins, usually from the upstream end (recession can also occur at the leading edge of the water stream, or from its both ends, either prior to completion of advance or after). The time interval between the surface stream arrival and its departure at a given location is termed the infiltration-opportunity time.

Table 1 Potential on-farm application efficiencies of irrigation systems.

<i>System type</i>	<i>Application efficiency (%)</i>
Surface irrigation	
Furrow	60–75
Level basin	60–85
Border	60–80
Sprinkler irrigation

Subirrigation	50–80

^aIncludes center-pivot and linear move systems with also low-energy precision application (LEPA).

^bIncludes drip, microsprayers and microsprinklers.

Furrow irrigation

In furrow irrigation, used mostly for row crops (such as cotton, maize and sugar cane), water flows in evenly spaced furrows or corrugates that are typically 0.1–0.3 m wide, spaced at 0.75–2 m (Fig. 1), on fields with slopes of 0.1–3%. The lateral furrow spacing should be smaller for sandy soils and larger for clayey soils. Furrow lengths may range anywhere from tens to hundreds of meters, depending on the soil type, slope and crop type. Shorter furrows are commonly associated with higher uniformity of water application, but result in increasing potential for runoff losses. Usually, the furrows are run in the direction of the predominant slope, normal to the contours, although this should be avoided on steep slopes where soil erosion may be severe. Inflow to irrigation furrows may be supplied from gated pipes or ditches (earthen or concrete). Siphon tubes are frequently used to convey and regulate water flow from ditches to individual furrows (Fig. 2). By creating a siphon, water flows through the tube, over the ditch bank, and into the furrow, as long as the tube outlet is lower than the water elevation in the ditch. Furrow inflow rate is controlled by tube diameter and the elevation difference between the ditchwater level and tube outlet. Gated pipes distribute water to furrows through evenly spaced outlets on the pipes. With earthen ditches, water can flow through a breach or other opening in the ditch bank to individual furrows or a smaller feed ditch that distributes water to several furrows. It is much more difficult to regulate flow through a breach in an earthen ditch than through siphon tubes or pipe gates. Sometimes only one of two neighboring furrows is continuously or alternately irrigated during consecutive irrigations. It can take a considerable period of time for the water to reach the furrow bottom end (the advance phase), meaning water has been infiltrating for a longer period of (opportunity) time at the top end of the field. This results in poor water application uniformity with high application at the top end and lower application at the bottom end. In most cases, the water application uniformity can be improved by increasing the speed at which water advances along the furrow through increasing flow rates. Increasing the advance rate not only improves the uniformity, but also allows application at smaller irrigation depths. Water commonly flows in furrows for short durations of several hours to full days during an irrigation, but shorter or longer durations may be used depending on furrow length and soil, water, and management considerations. Inflow rates for individual furrows vary in the range of approximately 10–100 L min⁻¹, again depending on soil (texture, surface roughness), slope, field length, and management. Ideally, water should advance across the field in approximately 25% of the total irrigation time to irrigate the field uniformly. The goal is to minimize tailwater loss while still allowing sufficient soaking time at the lower end of the furrow. Since soil erosion increases as field slope and inflow rate increase, flow rate must be carefully managed on fields with steeper slopes (greater than 1%). Low inflow rates and long irrigation durations may be needed to apply the desired amount of water during an irrigation on soils with low infiltration rates. Conversely, higher inflow rates are often needed on fields with low slopes or high infiltration rates, for the water to flow across the field and uniformly irrigate its upper and lower ends.

The advance phase of surge furrow irrigation consists of a series of about five surges (or cycles, e.g., on for 1 h and off for 1.5 h), each advancing farther than its predecessor, to get the water to the end of the furrow. Surge flow irrigation is often more efficient and can achieve reduced infiltration rates and faster water advance down the furrow than conventional furrow irrigation, thus increasing the water application uniformity along the furrows and reducing the minimal water application depths.

Fig. 1 Schematic of a furrow-irrigated field, where water flows in evenly spaced furrows or corrugates. From the 2005 edition.

Fig. 2 Furrow-irrigated sugar beet field, with water supplied by siphon tubes from a concrete ditch. From the 2005 edition.

Furrow irrigation requires lower capital investment, but greater labor than most other irrigation systems. Furrow irrigation is not well suited to automation as water flow rate must be adjusted for each furrow for each irrigation. However, automated valves and programmable controllers are used, including special surge (butterfly type) valves alternating the water supply to two sets of furrows.

Basin and border irrigation

Basin and border (sometimes termed 'level basin' 'border strip') irrigation systems are similar in that both involve a uniform sheet of water flowing over the soil. The main difference is that basin irrigation applies water to a nearly level field and may include ponding for extended time periods. With border irrigation, water flows between dikes that divide a sloping field into rectangular strips with free drainage at the end. The purpose of the dikes is to contain water as it flows across the field, unlike basin irrigation where the dikes pond the water (Fig. 3). In this respect, border strip irrigation can be considered as a hybrid of level basin and furrow irrigation.

Basins can be as small as a few square meters for a single tree or as large as several hectares with greater than 100 L s^{-1} inflow rates (Fig. 4). Basin size is a balance of soil infiltration rate, slope and water supply. Water depth in flooded basins varies about 5–20 cm, with typical depths of 10–15 cm. Efficient basin irrigation requires a level soil surface with uniform, not too coarse, soil texture and

Fig. 3 Schematic of a border-irrigated field, where a uniform sheet of water flows between dikes. From the 2005 edition.

Fig. 4 Level Basin flood irrigation of wheat.

adequate water supply, so the basin is quickly and uniformly covered with water. If the basin is not level, the higher elevation areas will receive less water than the low areas. If the basin infiltration rate is too large, water will slowly advance, causing large differences in infiltration opportunity time within the basin. Rice is cultivated mostly, in either rain-fed or gravity-irrigated, permanently-ponded, flat paddies (or terraces in mountainous terrains).

A special type of basin irrigation is a drain-back level basin. Drain-back level basins have a series of parallel basins that receive inflow from a shallow, 5–10 m wide ditch. After the first basin is filled, a gate opens to start filling the adjacent basin, which is at a lower elevation. Water near the inflow end of the first basin drains back to the inflow ditch and flows to the next basin. This procedure is repeated until every basin has been irrigated. The drain-back phase improves uniformity by reducing the amount of water that infiltrates near the inflow end and initially increasing the inflow rate to the next basin, which increases the surface stream advance rate.

Border irrigation systems are better suited for sloping fields than basin systems because water flows between dikes rather than being ponded within basins. The irrigated areas between dikes may be 3–30 m wide and up to 400 m long. The field slope between dikes (perpendicular to water flow direction) should be nearly level so water flows uniformly down the field. The slope along the dikes can be similar to furrow irrigation, but border systems often have slopes less than 0.5%. Typical inflow rates vary from 10 to 100 L s⁻¹, but vary widely depending on the size of the basin or border, soil texture and slope. If water inflow is cut off before the stream has reached the bottom end of the field, the stream continues to advance for some time, if it is deep enough, and if the slope is large enough, and the infiltration rate, soil roughness, and vegetative drag are small enough. This operating strategy increases the irrigation efficiency in level basins and in sloping border strips, where it reduces the amount of runoff.

Border and basin irrigation require less labor than furrow irrigation because water is supplied to a larger area with a single outlet.

Sprinkler irrigation

Sprinkler (sometimes termed ‘overhead’) irrigation applies water to soil by sprinkling or spraying water through the air on to the soil surface or on to the plants canopy. Water is pressurized and delivered to the irrigation system by a mainline pipe, which is often buried, so it does not interfere with farming operations. Sprinkler irrigation is used for a wide variety of plants, including field crops, orchard trees, lawns (golf courses), and pasture. Sprinkler systems are also installed for frost and freeze protection, for cooling plants, for the control of airborne dust and minimization of wind erosion, and for land application of wastewater (Hoffman et al., 2007; Keller and Bliesner, 1990).

Sprinkler Irrigation systems can be categorized based on their spraying mechanisms and on their portability. Many kinds of sprinkler devices are in use, such as impact sprinkler, spray pads, rotating pads and LEPA (low energy precise application) systems. They use a nozzle to control their discharge rate, its diameter and shape of its orifice, and the water pressure at the nozzle control the flow rate, size of water drops and the wetting pattern. These and the height of the sprinkler device determine the diameter of coverage and the distribution of water within the wetted region. The impact sprinkler in which the sprinkler head, driven in a

circular motion by the force of the outgoing water, pivots on a bearing on top of its threaded attachment nut, was invented in the US in the 1930s, and quickly found widespread use.

Three main portability categories of sprinkler irrigation systems are solid-set, set-move, and self-moving.

Solid-set systems may be installed for a single season for certain field crops or permanently for lawns, orchards, or permanent crops. Set-move systems are manually or mechanically moved to another part of the field after the irrigation set is complete in the present location. Self-moving systems such as center pivots or traveling guns apply water as the system slowly travels through the field.

Small drops are prone to drift in windy conditions and to evaporative losses. Large drops, on the other hand, resist wind drift, however, their impact energy may breakdown soil aggregates and form a seal (crust) on the soil surface which reduces infiltration and leads to runoff.

The application rate, determined by the sprinklers flow rate and their areal coverage, should not exceed the soil infiltration rate to avoid runoff, accounting for also the ground slope, i.e., lower on steeper slopes. Its recommended range is in between about 2 mm h^{-1} in 12% slope clayey soils to 50 mm h^{-1} in flat sandy soils. The time of operation per set should be selected to satisfy crop water requirements throughout the irrigation interval while minimizing deep percolation losses.

Sprinkler irrigation is often more efficient than surface irrigation, because water application is more controlled (Table 1). In hot or windy areas, however, sprinkler irrigation can have significant losses from evaporation and wind drift. Maintenance is also important for efficient sprinkler irrigation. Worn nozzles and leaking pipe connections reduce application uniformity and system efficiency.

Solid set sprinkler systems

Most solid-set sprinkler irrigation systems are designed to apply frequent (e.g., daily), small amounts of water to meet plant water needs. Water application rates can vary from approximately $2\text{--}6 \text{ mm h}^{-1}$ for field crops to $5\text{--}30 \text{ mm h}^{-1}$ for lawns applications. Capital costs are greater for solid-set systems than other sprinkler systems, because the entire irrigated area must be equipped with sprinklers and pipe. However, permanently installed systems can be automated to reduce labor and allow irrigation at any hour of the day, which reduces the risks for plants to be stressed. When properly designed, solid-set systems have high application uniformity. While solid-set systems are most commonly used with lawns, and landscape and permanent crops, these systems are also used for some high-value annual crops with low tolerance for water stress.

Solid-set system designs are as varied as the applications: small sprinklers may irrigate 20 m^2 , or large, gun-type sprinklers may be spaced 50 m apart. Plastic pipe is frequently used for buried applications, but it is also used in some aboveground applications. Aluminum, rigid and flexible plastic pipes (50–100 mm in diameter) are often used for field crops when the system is installed after planting and removed before harvest (Fig. 5). Most systems are divided into zones so a portion of the area is irrigated at one time. Solid-set systems for use in frost and freeze prevention, however, must be designed to water the entire area simultaneously.

The water application depth of a single sprinkler decreases with distance in a pattern in between elliptical and triangular which necessitates proper overlap between the wetted areas to achieve a good irrigation uniformity. Usually, the spacing between the laterals is larger than between the sprinklers along the lateral, creating a rectangular sprinkler arrangement. In such arrangement, and if the application pattern of a single sprinkler is distorted by winds, orienting laterals perpendicular to the prevailing wind direction is generally recommended for best overlap of the wetted areas. In no wind conditions recommended sprinkler and lateral spacing are about 45% and 65% of effective wetted diameters of the sprinklers (at average pressure along the lateral). At wind speeds exceeding 16 km h^{-1} , these both percentages reduce to about 30%.

Fig. 5 Solid-set sprinklers near Rio Vista, California, US.

Fig. 6 Schematic of a set-move-irrigated field, where the irrigation system is moved to the adjacent area after completing an irrigation set. From the 2005 edition.

Set-move sprinkler systems

Set-move sprinkler irrigation systems are designed to apply water slowly during the irrigation set (e.g., $4\text{--}6\text{ mm h}^{-1}$), which often lasts 8–24 h. After completing the irrigation set, the sprinkler system is moved to an adjacent area for the next set (Fig. 6). Adequate water has to be applied during an irrigation set to meet crop water needs until the system is moved back to the area, often in 7–10 days.

The common types of set-move irrigation systems are hand-move and towline systems. Hand-move systems can be a single sprinkler or a line of sprinklers. A line of hand-move sprinklers, sometimes called handlines is typically composed of 9- or 12-m long pieces of 75- or 100-mm-diameter aluminum pipe with a sprinkler mounted on one end or in the center. Individual pipes are connected to form an irrigation line, usually not more than 400 m long. After an irrigation set is completed, the line is disconnected, and each piece is moved by hand 10–20 m to the next set. A slight variation to the handline is the ‘dragline’ (‘towline’ or ‘skid-tow’ or ‘end-pull’). These systems have special connections between sprinkler pipes that allow the irrigation line to be pulled by a tractor to the next set. They were developed to reduce labor required to reposition laterals. The rigid couplers of the laterals are fitted with skids or a pair of wheels so the line can be pulled with a tractor. Stabilizers, outriggers or wheel-mounts, are used to keep the lateral from tipping and keep the sprinklers upright. The flexibility of the pipe and the couplers permit the lateral to curve slightly while being pulled to its new position.

Self-moving sprinkler systems

Self-moving irrigation systems include center-pivot, linear-move, and traveling gun systems. Center-pivot and linear-move systems are similar in design and appearance. These systems consist of one or more spans of sprinkler pipe (usually galvanized steel or aluminum) elevated by ‘A-frame’ wheeled towers. Span length varies from 30 to 65 m. The towers, powered by hydraulic or electric motors, elevate the sprinkler pipe 2–4 m above the ground (Fig. 7).

The center pivot has a stationary pivot point so the wheeled towers move in a circle, creating a typical circular pattern with, complete or sectioned, cultivated circles of same or different diameters and various colors viewed from above (Fig. 8). Crops are planted either in straight rows or in circles, conforming to the travel of the wheeled towers. Water and power are supplied to the system through the pivot point. Originally, most center pivots were water-powered. Later on, these systems were replaced by ones driven by electric motors, usually having a motor mounted at each tower. The outside set of wheeled towers sets the pace for the rotation. The inner towers between two segments use angle sensors to detect when the bend at the joint exceeds a certain threshold. When the angle is too large, the wheels rotate to keep the segments aligned. A typical center pivot in the USA (where they were invented in 1940) has eight spans, a total length of approximately 400 m ($\frac{1}{4}$ mi), and irrigates 50–60 ha. Typical periods for a full rotation last about 3 days, the outer edge of the system moving at a speed of about 1 m min^{-1} . Some center pivots are equipped with an additional corner span (arm) or an end-gun that irrigate additional areas in between the main wetted circular area and its inscribing square.

Center pivots are extremely popular, because water is uniformly applied to a large area with little labor. Furthermore, once a circular field has been irrigated, the center pivot is in position to start the next irrigation. System cost per irrigated area is reduced by increasing the total length of a center pivot, because irrigated area per unit length increases with distance from the pivot point. A 50 m span at the pivot point irrigates 0.8 ha, while a 50 m span that is 350 m from the pivot point irrigates 11 ha. Consequently, water application rate increases with distance from the pivot point, usually by increasing the nozzles diameter. Application rates often exceed the infiltration rate of the soil, generating runoff after consuming some surface storage in flat fields, which may limit

Fig. 7 Center pivot with drop tube sprayers.

Fig. 8 A satellite image of circular fields, of either $\frac{1}{4}$ or $\frac{1}{2}$ miles diameter, characteristic of center pivot irrigation, Kansas, US. Credit NASA.

center pivots use in fine-textured, clayey soils. Center pivots can also irrigate fields with undulating terrain that are difficult or impossible to irrigate by surface-irrigation methods; however, these conditions can create additional management challenges.

Early center pivots had impact sprinklers mounted on top of the irrigation pipe that required 5–6 atm (500–600 kPa). Most new systems have low-pressure nozzles (0.7–2 atm, 70–200 kPa) mounted on tubes ('goosenecks') that extend below the irrigation pipe (drop sprinkler heads), so nozzle height varies from 1 to 3 m above the soil (Fig. 7), thus limiting evaporative and wind drift losses. Drop tubes can also be used with drag hoses or bubblers that release the water directly on the ground between crops, sometimes associated with the construction of small dams along the furrow length ('furrow diking').

Manufacturers make numerous types of low-pressure nozzles with fixed or spinning spray plates (LEPA) that provide a wide range of application rates and water-droplet sizes to meet field conditions and operator preferences. A common feature to all nozzle types is a pressure regulator, which maintains constant nozzle pressure as the system travels across a field with varied elevation. Many modern center pivots feature GPS devices for applying VRI.

Linear-move systems (also termed 'lateral move') have a control unit on one end, or in the center on longer systems, that moves the towers in a straight line to irrigate rectangular shaped fields. Power is supplied by an electrical drag cord or by an engine-powered generator mounted on the control unit. Water is typically supplied to the drive unit by a drag hose connected to a buried or aboveground pipe. Drive units can be equipped with a pump so water can be supplied from an open ditch flowing parallel to the travel direction, but this is not commonly used, because it requires a nearly level ditch. System cost per irrigated area is reduced by increasing the distance the system travels. Since hose length is limited to approximately 150 m, the system can move 300 m before the hose is connected to the next riser. Similar to set-move and center-pivot systems, adequate water must be applied to meet crop needs until the linear-move can irrigate the area again.

A manual, old version of a linear-move system and an upgraded version of a handline, still in use, is a wheel line (or 'side roll') comprised of a series of aluminum pipes (100–125 mm in diameter), usually each with a large-diameter wheel of 1.5–2 m mounted in its center or on end, and self-levelling sprinklers along its length, between the wheels (Fig. 9). Water is supplied at one end using a hose. The pipes serve both for conveying the water and as an axle for rotating all the wheels. A motorized drive system (often located near the center of the wheel line) rotates the clamped-together pipe sections as a single axle, rolling the whole wheel line. Manual adjustment of individual wheel positions may be necessary if the system becomes misaligned. After sufficient irrigation depth has been applied to one strip of the field, the hose is removed, the water drained from the system, and the assembly rolled, so that the sprinklers are moved to a different position across the field. This system is less expensive than modern center pivot and linear-move systems, but much more labor-intensive to operate as it does not travel automatically across the field. Wheel line systems are limited (by the wheels' radius) in the height of crops that can be irrigated.

A traveling gun has a large-capacity sprinkler on a cart that is pulled across the field by a cable, by the water-supply hose or by a tractor. Guns are similar to rotor sprinklers, except that their larger nozzle diameters are in the range of 10–50 mm, they generally operate at very high pressures of 2.75–9 atm (275–900 kPa) and their flow rates are 3–76 L s⁻¹.

These systems irrigate an area 50–100 m wide and up to 400 m long. A traveling gun can be considered a set-move system because water is applied as the cart moves across the field and then the system is moved to another area in the field for the next irrigation set. For cable-tow systems, a winch on the cart winds the cable, pulling the cart and a soft hose across the field. A hose-reel system pulls the cart as a plastic hose is wound around a reel on a trailer anchored at the end of the run. The reel or winch is powered by an engine or a water turbine. Smaller versions of traveling guns are available for irrigating sports fields and small pastures.

Fig. 9 Side-roll (wheel line) irrigation system in Idaho, US.

Lawn sprinkler systems

Lawn sprinkler systems are permanently installed in residential lawns, gardens of public buildings, public parks, cemeteries, and golf courses. Usually, most of the components of these irrigation systems are buried, to not interfere with the lawn users and for aesthetic purposes. The two main types of sprinklers used in lawn irrigation are pop-up spray heads and rotors. Spray heads have a fixed spray pattern, while rotors have one or more streams that rotate. Spray heads are used to cover smaller areas, while rotors are used for larger areas. On lawns, pop-up sprayers or sprinklers are usually installed with their tops flush with the soil surface. On activation of the irrigation, the head will pop up out of the ground and water the lawn until the valve closes, the water pressure in the lateral line declines, and the sprayer (sprinkler) head retracts back into the ground. In flower beds or shrub areas, sprinklers are usually mounted on above ground risers. Garden irrigation systems usually consist of few zones divided by their type of plants and water emitters, possibly including also zones with drip irrigation, bubblers, or other types of equipment besides sprinklers. Nowadays, most lawn and garden irrigation systems operate automatically using an irrigation controller and electric solenoid valves.

As opposed to the permanently-installed systems described above, many types of moveable (traveling) hose-end sprinklers are also used for watering lawns and gardens. Some have a spiked base temporarily anchoring them in the ground, while others have a sled base designed to be dragged while attached to the hose, usually connected to an outdoor water faucet.

Micro-irrigation

Another type of pressurized irrigation is micro-irrigation (MI or 'localized irrigation'). Water is applied frequently (daily, or even few times a day—'pulsed irrigation') at low flow rates directly to the plants root zone with minimal evaporation, deep percolation and runoff losses. Water drips from emitters in plastic pipe or tape, or bubbles or sprays from small emitters that only wet a portion of the soil surface (Dasberg and Or, 1999; Hoffman et al., 2007; Lamm et al., 2006; Nakayama and Bucks, 1986). These systems are typically automated, which facilitates the frequent water application that maintains optimum soil-water contents near the plants, reduces deep percolation losses and increases water use efficiency. Filtration is important for MI, because mineral deposits, algae and bacteria can plug the narrow openings on drip emitters, bubblers, and micro-sprayers (several optional sand separators, media and screen (or disc) filters are depicted in Fig. 10). The required level of filtration depends on the size of the water paths (labyrinths and orifices) of the water emitters and on the irrigation water quality. Chemical treatment may also be necessary to reduce mineral or biofilm deposits.

MI is popular for permanently installed systems that irrigate trees, vineyards, orchards, and shrubs, but in the last decades its application for field crops and vegetables irrigation is increasing. MI systems are appropriate for undulating terrains and fields with irregular shapes, providing the highest field-scale, water distribution uniformity. Most MI emitters are also available as pressure-compensating devices. MI can be adapted to soils of both very low and very high infiltration rates, and to almost any

Fig. 10 Layout of a drip irrigation system and its main components.

cropping technology and climatic conditions. However, since the installation costs of MI systems are higher than those of surface and sprinkler irrigation systems, at present MI is used for irrigating mostly high-value crops, i.e., vegetables and perennial crops, mainly orchards and vineyards. With increasing demands and competition on dwindling water resources and the need to minimize environmental consequences of irrigation, MI is expected to play a more important role in the future.

Drip irrigation

Drip irrigation (DI, or trickle irrigation) emitters (drippers) are either integrated (in-line) within polyethylene pipes (laterals, driplines) at regular intervals or attached to the outside (on-line, 'button drippers') of the pipe at desired locations. In addition to the filters mentioned above, other system components include the main, submain and lateral lines, pressure regulators, automatically or manually operated water valves, air (and vacuum) relief valves, end stoppers, and flush valves (Fig. 10). Modern automatic systems include also an irrigation controller used for controlling the solenoid valves of the various irrigated sections and filter back flushing, and a fertilizer application system with a backflow prevention device. Drippers regulate their water flow rates by friction and turbulence head losses created by their narrow labyrinth-type flow paths and orifices. Typical flow rates vary from 0.5 to 8 L h⁻¹. Pressure-compensating emitters maintain a constant flow rate as pressure varies from approximately 0.7 to 2 atm (70–200 kPa), and a non-drain feature keeps the driplines water-full at the end of irrigation, preventing also vacuum and suction of soil particles into the drippers.

Drip tape is usually thin-walled (0.1–0.5 mm, recyclable) plastic tubing (10–30 mm in diameter), with outlets at 10–60 cm intervals. Flow rates usually vary from 1 to 4 L h⁻¹ m⁻¹. Typical operating pressures for drip tape is 0.35–1 atm (35–100 kPa).

In orchards and gardens, trickle rings, i.e., circular driplines with evenly distributed drippers are sometimes placed around the base of the trees or shrubs.

Microtubing irrigation is another type of drip irrigation common in gardening, nurseries and greenhouses. Flow rates are regulated by the plastic tubing's length and diameter, and stakes are usually attached to the end of the tubing to anchor it to the ground. Sometimes the (split) tubes are also used with drippers ('spider drip').

In Subsurface Drip Irrigation (SDI) driplines or drip tapes are installed below the soil surface at depths of 10–50 cm, where there is less opportunity for damage. SDI also reduces evaporation losses and improves weed suppression, facilitates shallow soil tillage and other planting, spraying and harvesting operations. Thus, the buried driplines and drip tapes can be used for several seasons or retrieved after a single season, depending on crop types and farming practices. SDI is more suitable for use with treated wastewater (TWW) than on-surface DI. On the other hand, plant germination and establishment can be challenging in sandy soils with too larger dripline burial depths. Sometimes, also with on-surface DI, a special germination irrigation with usually a sprinkler irrigation system is required. An alternative practice with on-surface DI is to shift the driplines to the planting rows for the germination irrigations. Additional disadvantages of SDI are potential dripper plugging by intruding plant roots and rodent damage. In many circumstances yield increases have been observed under SDI when compared to surface, sprinkler, and even on-surface DI systems.

Driplines and drip tapes can be regarded as water point or line sources depending on the ratio between the drippers' spacing and the soil capillary length; if smaller than one, it resembles a line source. The soil capillary lengths of most agricultural soils vary between approximately 10 cm for sandy soils to 100 cm for structureless, clayey soils with common values of 20–40 cm for loams and fine sands.

The agronomic design of drip irrigation systems involves decisions regarding the spacing between the drippers along driplines and between driplines and the burial depths of SDI driplines, all should be smaller in coarse texture, sandy soils, and for plants with small root systems (DIDAS: <https://app.agri.gov.il/didas/>). The spacings between driplines and between drippers, and the number of driplines per planting bed or tree row should correspond to also the planting configuration and density (Fig. 11). Irrigation frequency should be usually higher in sandy soils and for plants with small root systems, and irrigation dosing should account for the plants water requirements and for proper salt leaching of the localized wetted bulb hosting the active root system. Drip irrigation is often combined with fertigation and plastic mulching, further reducing evaporation and increasing irrigation and fertilizer application efficiency. In addition, DI minimizes the incidence of many diseases that are spread through water contact with the foliage and highly-saline water drops injury in sprinkler irrigation.

Bubblers and microsprayers

Bubblers, microsprayers and other non-drippers low-pressure, MI devices (microsprinklers, foggers, and jets) are often used for irrigating trees, shrubs, or ornamental plants, applying water to larger areas than drippers. Bubblers apply a small stream of water to the soil surface at flow rates of up to 250 L h⁻¹ irrigating a few meters diameter areas, depending on orifice size, type, and pressure. Usually, a small basin (pit) is used to control the distribution of the ponded water. Microsprayers (and microsprinklers) apply a fine spray or mist with similar flow rates and wetted areas as bubblers. Nozzle sizes typically range from 0.5 mm to 2 mm and plugging problems are usually less common as compared to DI. The MI emitters are typically connected to polyethylene pipes with a barbed connector and are attached to hard plastic risers or mounted on stakes. As for drip irrigation, the other MI devices are used to irrigate mostly sandy soils of limited lateral, capillary water flow.

Fig. 11 Drip irrigation of a young mango plantation with two driplines for a tree row.

Subirrigation

Subirrigation applies water below the soil surface by raising the water table into or just below the plant root zone, so that water flows upward into the root zone by capillarity (Hoffman et al., 2007). As capillary rise is usually limited to few tens of centimeters, subirrigation can only be used on relatively flat lands, where also permanent shallow water tables already exist. Thus, it is typically used in conjunction with subsurface drainage, mostly in humid regions without salinity problems. Subsurface drainage lowers the water table and removes excess water through open ditches or perforated pipes (Skaggs and van Schilfgaarde, 1999; Waller and Yitayew, 2016). Water-table depth can be controlled by regulating water levels in open field drainage ditches or by controlling the head on subsurface drainage pipes with adjustable weirs. During wet periods, the water table is lowered so the root zone remains unsaturated. During dry periods, water is pumped into the drainage system to raise the water table and provide additional water for plant growth. In some situations, drained water can be stored for use when irrigating.

Fertigation (chemigation)

Fertigation is the processes of applying water-soluble, NPK and micronutrient, fertilizers via the irrigation system, and chemigation refers to other agro-chemicals such as insecticides, herbicides, and fungicides (Bar-Yosef, 1999). The chemicals may be added, with the aid of a dedicated tank and liquids injectors such as diaphragm pumps, piston pumps, or Venturi aspirators, constantly whenever the system is irrigating or at specified times, when needed. A proportional (to the water discharge rate) injection mode maintains constant concentrations in the irrigation water. It is common to stop the fertigation before irrigation ends in order to clear the fertilizers out of the irrigation system. The flexible and continuous application of plant nutrients, combined with water application, both corresponding to plant needs, increase their nutrient use efficiency, thus, decreasing the amounts of fertilizers (and other agro-chemicals) needed and consequently their leaching into groundwater and surface water resources.

Fertigation (chemigation) is possible with mostly drip and sprinkler irrigation as these irrigation systems can be managed to quickly and uniformly irrigate small amounts of water, which communicates with continuous application of fertilizers (and other agro-chemicals). Drip irrigation is more suitable for fertigation (chemigation), since the direct contact of the sprinkled (sprayed) water with the plants canopy can be problematic. Sometimes, in rainy regions, DI systems are used just for fertigation, even if water application is not required.

Subsurface drip irrigation systems can be used for also improving soil aeration by air injection with a compressor (or blower) or by adding air or oxygen (nano) bubbles or hydrogen peroxide to the irrigation water (a practice termed oxygation or oxygenation) (Ben-Noah and Friedman, 2018).

Salinity hazards and management

Even if using non-saline, good quality irrigation water, evaporation and selective water uptake causes salinization of the soil solution, which may cause osmotic stress to plants and impedes their water uptake, growth and yield production (Hoffman et al., 2007). Salinity problems are more closely associated with climatic conditions, soil and water chemistry than with the type of irrigation system; however, the irrigation system can accentuate salinity problems and affect how salinity is managed. Basin and border irrigation can uniformly leach salts from the soil when infiltration is uniform. Sprinkler irrigation can also uniformly leach salts, but sprinkling can injure sensitive plants when highly saline water is applied to foliage. Furrow irrigation leaches salt from soil below the furrows, while increasing salt concentrations in the beds (ridges). Tilling before planting crops tends to minimize salinity problems by mixing salts in the soil. Salt concentration tends to increase radially from a point-source dripper or laterally from a line source. Well-managed drip irrigation can minimize salt-induced stress by maintaining a high soil-water content with frequent irrigations.

Using all irrigation methods an additional irrigation depth should be applied, the leaching requirement (LR, or leaching fraction, LF), either in each irrigation or periodically, for leaching the saline soil solution. Yet, excessive leaching is undesirable, as it wastes water, and as it introduces more salts into the soil, which may eventually reach groundwater and surface waters, degrading their agricultural and domestic use quality and harming ecosystems. In semi-arid regions, with also a rainy season, a possible, beneficial salinity management strategy is to accumulate salts in the root zones during the dry irrigation seasons and to (partly) rely on rainfall events to leach the salts and prevent inter-annual salinity buildup.

Capillary rise of saline groundwater from shallow water tables is another source of root zone salinity. These circumstances are usually associated with water contents being too high and aeration problems (hypoxia). The solution to both salinity and poor aeration problem is to control the water table depth with an artificial drainage system of open ditches or buried perforated pipes.

Another problem often associated with salinity in arid and semi-arid regions is soil sodicity, caused by using irrigation water rich in sodium and resulting in destruction of soil structure and reduction of the soil infiltration capacity, which limits the applied irrigation rates.

Choosing an irrigation method

Choosing an irrigation method, among the above-described various methods and their variants, is a difficult task. The right selection depends on soil, water, and climatic conditions, as well as crop types, user knowledge and preference, capital and operating costs, and infrastructure availability. No system is best for all situations. In a broader sense, an irrigation method includes not only the system's hydraulic hardware, but also 'software' aspects of operation mode, technology and support infrastructure. These may include guidance for system design, installation, operation, and maintenance, and for irrigation scheduling and other irrigation-related agricultural practices. In addition to the grower benefits and welfare, regional, hydrological and environmental, considerations should also pay a role, within the imposed constraints (Hoffman et al., 2007).

Some typical advantages and disadvantages of irrigation systems are shown in Table 2. Sprinkler or micro-irrigation are often better choices than surface irrigation on sandy soils, where excessive deep percolation is a problem. Surface irrigation may be better in arid, windy areas, where wind and evaporation losses can be significant. Surface irrigation offers less control of application depth, so small, frequent irrigations are not practical for water-sensitive crops, which are better suited to micro-irrigation, solid-set, or center-pivot systems.

Conclusion

Irrigation increases yields and ensures the reliability of crop production—approximately 40% of the world's food is grown on irrigated land, which accounts for only about 20% of the world's land used for crop production. Various irrigation methods have been developed over time to meet the irrigation needs of certain crops in specific areas. The three main methods of irrigation are surface, sprinkler, and micro-irrigation (including drip). In surface irrigation, water flows over the soil by gravity. Sprinkler irrigation applies water to soil by sprinkling or spraying water droplets from fixed or self-moving systems. In micro-irrigation, used at present in only few percent of irrigated land, small water volumes are applied by dripping, bubbling, or spraying. With increasing demands and competition on dwindling water resources and the need to minimize environmental consequences of irrigation, sprinkler, micro and especially drip irrigation are expected to play a more important role in the future. In addition to transition from surface to sprinkler or drip irrigation, irrigation system improvements, better irrigation design and scheduling, and more intense, proxy and remote, soil and plant sensing should be practiced.

Table 2 Advantages and disadvantages of common irrigation methods^a.

System type	Advantages	Disadvantages
<i>Surface irrigation</i>	Avoidance of canopy wetting; suitable for short-term water supplies; low capital, energy and maintenance costs	Low distribution uniformity; high evaporation, deep percolation and runoff losses; conveyance losses; large irrigation depths; unsuitable for sloppy terrain; requires initial landforming operations; not suitable for sandy soils
Furrow	Water flows in small channels: less evaporation losses	High labor and initial landforming operation costs; requires experience to operate; possible runoff and deep percolation losses; possible soil erosion; salt accumulates on ridges
Level basin	Less labor costs than furrow	Ponded water; high evaporation losses; possible plant diseases
Border strip	Less labor and less runoff than furrow; easier to manage infiltration depth	Water flows over entire soil surface; requires repair of ridges and supervision during irrigation
<i>Sprinkler irrigation</i>	Good distribution uniformity; smaller irrigation depths; less deep percolation and runoff losses; allows frost and freeze protection and cooling; simulates natural rainfall; better suited for mechanization and automation	Evaporation losses; wind drift; not suitable for steep slopes; not suitable on soils with low infiltration rates; risk of soil surface sealing, runoff and soil erosion; canopy and fruit wetting; problematic with saline water; requires higher water pressure; high capital, energy and maintenance costs
Solid set	Fits odd-shaped fields; low labor costs	High capital cost; system may interfere with field operations
Set-move	Lower capital costs compared to solid set	More labor than other sprinkler systems; poor uniformity in windy conditions; greater irrigation depth
Self-moving ^b	High distribution uniformity; less wind drift effect; low capital and labor costs	Not suitable for odd-shaped fields; circular center-pivot—irrigated fields leave unused land
Traveling gun	Less interference with soil tillage and agricultural operations; low energy and labor costs	Low distribution uniformity; not suitable for clayey soils; possible soil surface sealing and runoff; not suitable for odd-shaped fields; requires high water pressure
<i>Micro-irrigation</i>	High distribution uniformity; supports frequent applications; low irrigation depths; maintains favorable root zone conditions; allows fertigation; reduced evaporation and runoff losses and soil erosion; suitable for sloping terrain and all soil types; suitable for greenhouses and nurseries; suitable for automation	Not suitable for densely planted crops; requires clean water or treatment and filtration; interferes with soil tillage and agricultural operations; vulnerability to mechanical and animal damages; high capital and maintenance costs
Micro-sprayers	Allows frost and freeze protection and cooling	Evaporation losses; wind drift; canopy wetting
Bubblers	Avoidance of canopy wetting; good weed suppression; improved trafficability	Poor flow rate control and distribution uniformity
On-surface drip	Allows mulching; avoidance of canopy wetting; good weed suppression; suitable for fertigation; improved trafficability	Restricted root zone; low soil water storage; salt accumulation near plants
Sub-surface drip	Lowest evaporation losses; allows mulching; less interference with shallow soil tillage and agricultural operations; avoidance of canopy wetting; best weed suppression; best for TWW application; best for fertigation, chemigation and oxygation; saves driplines removal labor; best trafficability	Restricted root zone; low soil water storage; salt accumulation above drippers; problematic seed germination and plant establishment; increased deep percolation losses; limited dripper application rates; limitations for crop rotation; no visual inspection; potential rodent damage

^aThe general information related to the three main irrigation systems is given in italics.^bIncludes center-pivot and linear move systems with also low-energy precision application (LEPA).

Abstract

In this chapter, we describe research for understanding how living systems function in the soil–plant–atmosphere continuum (SPAC). Through process-based modeling and earth observations it is evident that whole ecosystems function as living entities. Process-based models and observations at the cellular to plant canopy level of water, energy and carbon exchange have given us a significant understanding of how living systems function through the SPAC—creating and maintaining their biomes. However, a major and continuing challenge is how SPAC processes scale up to the regional and global scales. We provide an insight to this scaling challenge by describing how water movement, key to sustaining life on Earth, is being quantified at multiple scales, and by discussing the need to incorporate remote sensing as a means of bridging from plant level water use to whole ecosystems and up to global scales. To accomplish this scaling, SPAC research requires integrating multi-sensor remote sensing data over the full electromagnetic spectrum, incorporating commercial satellite observations, and employing not only process-based models but data assimilation, and machine learning techniques with cloud computing.

Key points

- Water is an essential ingredient for life on Earth.
- The interaction of this water with energy is the cornerstone of our understanding of how soil-plant-atmosphere continuum (SPAC) interacts with its environment.
- The greatest value of complex SPAC models lies in improving our understanding of key processes and using this knowledge to derive intermediate models with fewer parameters and wider applicability.
- Scaling from the small spatial scale of direct measurements (meters to tens of meters) up to large regions (thousands of kilometers) requires use of numerous remote-sensing systems.
- Studies of the SPAC are interdisciplinary (involving research in areas that are not claimed by existing disciplines) and multidisciplinary (requiring collaboration among scientists from numerous disciplines).
- The future in advancing SPAC research will be strongly tied to the integration of spatial and temporal information from Earth observations, as this is the only means of bridging both spatial and temporal scales from plant level processes up to the global scale.

Introduction

The dominant distinguishing feature of the Earth, in comparison with all other celestial bodies we observe, is the presence of life. Humans, as a part of life on Earth, attempt to understand all of the life system, albeit from an anthropocentric perspective. Lovelock (1987) proposed a perspective that was unsettling to some and appealing to others when he suggested that the entire Earth may be functioning as a living organism. As our integrative understanding of living systems within the soil–plant–atmosphere continuum (SPAC) grows, the idea that a whole ecosystem can function as a living entity becomes more acceptable.

Consider a terrestrial ecosystem on land: The most essential ingredient for life on Earth is water and most of the water is not on the land. However, a rapid, long-distance system for transporting water from oceans to land is available through the atmosphere, much like the xylem system in a tree, which transports water long distances (relative to cell sizes) from the soil to the leaves high above the ground. This long-distance atmospheric transport system is driven unceasingly by the uneven, solar heating of the Earth. On the land, where many organisms reside, water moves much more slowly through the soil than through the atmosphere and this provides an essential storage reservoir that maintains the critical continuous flow of water to plants in the presence of fluctuations in the atmospheric supply. The rapid atmospheric transport system that is so critical to moving water from the ocean to the land also fluctuates wildly over the life span of most organisms. The combination of a small-storage, highly fluctuating system for rapid global transport in the atmosphere and a large-storage, stable, slow-flow buffer in the soil redistributes water over the Earth to sustain life on land. This is a highly structured system, like an organism. Furthermore, the living systems exert a strong influence on this larger system to enhance their functioning, just as we humans modify our environment to improve our lot.

Water is the most obvious component of the SPAC, and the interaction of this water with energy is the cornerstone of our understanding of how life interacts with its environment. Every schoolchild learns the water cycle: evaporation of liquid water from surfaces supplies water vapor to the atmosphere, where air currents lift this water to heights that cool it and cause condensation of the water vapor back to the liquid form of droplets, which fall back to the Earth to be recycled. The extraction of energy from the surface by evaporation and the release of energy to the atmosphere by condensation represent the primary means by which the energy from the sun ultimately warms the atmosphere. This 'latent heat,' which is associated with the change of phase of water between liquid and vapor states, and not a temperature change, provides the key feedback between water and energy cycles that stabilizes the soil–plant–atmosphere system, permitting it to sustain life.

Materials such as water flow through the ecosystem seamlessly, moving from place to place, serving innumerable functions, and consuming or releasing energy to achieve a phase suitable to the medium that contains it. This is the SPAC; 'continuum' here does not refer to the material storage forms so apparent to our eyes such as plant leaves or roots, lakes, raindrops, the soil itself, or even the air we breathe; rather, it refers to the unimpeded flow of many forms of material and energy throughout an elegant system for sustaining life on land. Animals are as much a part of this system as plants, but in this article, plants are our emphasis. This ceaseless flow of material and energy sustains life at every level; from the molecular interactions that sustain and mutate the genetic 'memory,' to cellular processes that make up whole organisms, to the global level of a living, breathing planet.

Living systems cycle matter through the SPAC and themselves to create and maintain their structure and extract energy for powering their life functions. All material necessary for sustaining life is cycled on all spatial levels from subcellular to global. The connectedness and functioning of the SPAC can be illustrated by reference to water, the most critical mass constituent to life on Earth. However, understanding the SPAC through water will necessarily involve some considerations of at least carbon and energy.

Fundamental principles

Two general principles are indispensable for studying the SPAC: (1) the conservation principles that take the form of mass and energy 'budgets,' and (2) the transport principles that relate the flow of some quantity to the difference or gradient of other quantities that influence or 'force' the flow and describe the 'state' of the exchange process.

The principles of conservation of mass and energy are the backbone of integrative studies of the SPAC. Because mass and energy can take many forms as they move throughout the SPAC, and even interact with each other, budgets are constructed to quantify the stores and flows of important life-enabling constituents such as water, carbon, or energy. A budget is simply the application of the conservation principles (mass or energy) to a specific system that must be carefully defined. This system may be defined as a leaf, a community of plants, or even the entire Earth. Like balancing a bank account, a budget is a formal statement of the following: Incoming quantity minus outgoing quantity equals the increase in storage of the quantity in the system. In the case of water (W), carbon (C), and energy (E), the budgets become the following:

$$\begin{aligned}W_{IN} - W_{OUT} &= \Delta W \\C_{IN} - C_{OUT} &= \Delta C \\E_{IN} - E_{OUT} &= \Delta E\end{aligned}$$

The intertwined budgets of water, carbon and energy inflow, outflow and storage within the soil–plant–atmosphere system are shown in Fig. 1. Understanding the SPAC through the role of water will involve simultaneous consideration of carbon and energy budgets on a spatial scale appropriate for living systems.

Fig. 1 The interlocking energy and mass budgets for water, carbon, and energy in the soil–plant–atmosphere continuum. Altering individual components can cascade through the system and affect many seemingly unrelated factors.

Consider the energy budget: energy can exist in many forms as it flows through the soil–plant–atmosphere system, and the energy budget represents a way to keep track of the energy, no matter what its form. The rate of energy flow (joules per second = watts) per unit of area (meters squared) is a convenient way to describe the energy budget for a particular land area, because the size of the area does not matter and the emphasis can be on the energy exchanges. Some fraction of the radiant energy from the sun and surroundings can be absorbed by a leaf (this is referred to as the net radiation) and be transformed to the following: (1) sensible heat energy that is convected away from the leaf by moving air that is cooler than the leaf; (2) Sensible heat that is conducted into the leaf itself altering the temperature of the leaf; (3) latent energy in molecules of water that are converted from liquid to vapor inside the leaf as they are transpired (evaporated) from the leaf; and (4) biochemical energy in the form of organic compounds such as sugars and starches created through photosynthesis and other physiological processes to sustain life. These components of the leaf energy budget are shown in Fig. 1.

The transport principle simply states that the flow of some quantity such as water is equal to an appropriate ‘driving force’ divided by a resistance to transport exerted by the various media through which the quantity moves. The transport principle is more difficult to use than the conservation principle because the ‘driving forces’ and transport resistances depend on the characteristics of the system and mechanism of transport. For example, the diffusion of liquid water depends on the water potential difference across a hydraulic transport resistance, whereas the transport of water vapor depends on the water vapor pressure difference across a diffusive transport resistance. In addition, movement of liquids or vapor by mass flow is ‘driven’ by pressure differences across transport resistances. In general, diffusion is an effective mode of transport over small distances, but mass flow can move materials and energy over longer distances. Heat transport is driven by temperature differences. The relevant thermal resistance depends on whether the heat is moving through a solid such as soil (conduction, which is analogous to diffusion), or through a moving fluid such as air (convection, which is analogous to mass flow and is a much more rapid transport mechanism than diffusion). Heat transport by radiation depends on still-different formulations. Thus, much research on the SPAC relates to determining appropriate transport resistances and state variables for characterizing the flow of important quantities throughout the system. A complete understanding of this soil–plant–atmosphere system is a formidable task, but such an understanding will improve the ability of humans to make choices that will sustain a diverse and resilient ecosystem, upon which our survival depends. The fundamental concepts of energy and mass conservation and transport relations constitute the theoretical backbone of environmental biophysics (the study of the SPAC) (Campbell and Norman, 1998).

Water in the soil–plant–atmosphere continuum

The smallest spatial scale that is usually associated with the SPAC is a field plot (square meters to thousands of square meters) from the bottom of a root zone (a few meters deep) to a few tens to hundreds of meters above the top of the vegetation. Although individual studies may use smaller systems such as individual leaves or potted plants to reveal mechanisms, the scale of at least a small field is required to encompass most of the essential components of the natural SPAC and yet be accessible to direct measurement. Researchers generally use formulations nearly identical to those measured in field plots to represent idealized patches of the Earth’s surface thousands of square kilometers in size; then, they combine these patches to understand better the

human influence on global climate processes. Typical time scales for small-scale studies vary from minutes to months and years. On these spatial and temporal scales, researchers attempt to measure all the important flow and state variables, which are used to validate models that can be applied in systems that cannot be measured directly. After all, society cannot afford to measure everything everywhere, but will support measuring some things in many places and many things in a few places. In such a system with unbounded complexity, quantification must proceed with an attitude of humility and openness to unexpected possibilities.

The transport and storage of water in the SPAC are shown in Fig. 2. The flow of liquid water from the soil into the plant depends on the plant having a lower water potential than the soil; thus, the soil water potential determines the availability of soil water for diffusion into the plant. The water potential is the amount of energy (joules) that can be obtained from moving a mass of water (kilograms) to a pool of pure water at atmospheric pressure and specified elevation; and in the soil and plant it is usually negative, indicating that energy must be expended to move the water. As soils dry, the water potential decreases, making it more difficult for plants to obtain the water they need to grow. The soil water potential is related to the water content of the soil through the ‘moisture-release curve,’ which varies from soil to soil. Moisture-release curves have been measured for many different soil types. Typically, soils can provide an amount of water to plants from storage that is equivalent to about 5% (sands) to 20% (silt loams) of the plants’ rooting depth. Thus, for a plant rooted to a depth of 1 m, soils can provide approximately 50–200 mm of water to the plant. With evapotranspiration rates of 2–10 mm per day, soils can store enough water to sustain plants for weeks to months without rainfall or irrigation.

Once water enters the plant through its roots, it moves through the plant vascular system to the leaves if the leaves have lower water potentials than the roots. Since the transport resistance to mass flow in the stem xylem is usually less than the transport resistance to diffusion through the root, and the flows through both root and xylem must be equal according to conservation principles, the water potential difference from the soil to the root xylem will usually be greater than the water potential difference from the root xylem to the leaf.

Water is lost from plants through pores in the leaf surfaces, called stomata. Evaporation from cells just below the stomatal pores (referred to as transpiration) draws water from the leaf cells, which in turn are hydraulically connected to a continuous water column down to the roots. As water is transpired through the stomata, additional water is drawn through the xylem to replace it, very much like suction applied to a straw in a soda. Of course, this evaporation that occurs just below the leaf surface consumes most of the Sun’s energy that is absorbed by the leaf, because water vapor molecules carry away latent energy that was not contained in the liquid water that came up from the roots. Although plants lose most of their water through these stomatal pores, it is unavoidable because these pores must open for carbon dioxide to enter into the leaf and supply photosynthetic tissue with the carbon needed to ultimately build the plant itself and supply animals with a source of life-sustaining food. Furthermore, leaf transpiration can also serve to moderate leaf temperature changes as the environmental air temperature varies over a wide range; this allows leaves to

Fig. 2 Water movement and storage in the soil–plant–atmosphere continuum. The graph on the right indicates the decrease in water potential that occurs as water moves from the soil to the atmosphere. On the left the three components of the soil–plant–atmosphere system are listed with the major factors for each that should be considered in a model of intermediate complexity.

function above air temperature under cool conditions, and below air temperature when it is hot so that leaf biochemistry, including photosynthesis, operates closer to optimal conditions. While the flow of liquid water from the soil to the leaf is proportional to water potential differences, the flow of water vapor from inside the leaf to the leaf surface is proportional to water vapor pressure differences. At the water-air interface inside the leaf, a near-equilibrium exists between the liquid water and the water vapor in contact with it. Although different processes are used to describe water movement in different parts of the system, the flow of water is continuous across these discontinuities of processes.

A very small amount of the water that passes from the soil to the atmosphere through the plant remains in the plant as storage as the plant grows (less than 5%). An even smaller amount of the hydrogen and oxygen in the water taken up from the soil remains in the plant in the form of organic molecules synthesized by the plant.

Water that exits the stomata must pass through a thin, still-air layer adjacent to the leaf, called the leaf boundary layer, and be transported through the canopy space by turbulent mixing along the path of decreasing water vapor pressure. Ultimately the water vapor exits the plant canopy, passes through the planetary boundary layer in the lower few thousand meters of the atmosphere, and is lifted high into the atmosphere, where it condenses into clouds and eventually falls back to the Earth as precipitation to repeat the cycle.

Small-scale observations and model building

In plant-environment studies, research derives and validates the transport principles on small, manageable systems in the laboratory or in field plots where direct measurements are possible. These principles are then assumed to apply at the ecosystem and global levels, where direct measurements are not possible, to obtain estimates of the important flow or state variables to quantify human impacts.

Consider the measurements that are necessary to understand the cycling of water in the SPAC. Precipitation falls on a field and either runs off the soil surface to streams or infiltrates into the soil itself (studied in the discipline of hydrology). The infiltrated water may be stored in the soil matrix (soil physics), evaporated from the soil surface (micrometeorology), transpired from plants (plant physiology), or drain below the plant root zone. Water that drains below the plant roots becomes part of the groundwater system (hydrogeology) and may reenter rivers (hydrology). Plants are sustained by the water stored in the soil, and the quantity of this storage depends on the type and condition of the soil. Nearly all the water taken up by plants is transpired to the atmosphere at a rate that depends on solar radiation absorbed, weather variables, and the amount and health of the vegetation. The amount of vegetation is estimated from the fraction of ground area covered by plants (vegetative cover). By keeping track of the daily water budget (Fig. 1 and Table 1), the amount of water stored in the soil can be estimated, and in turn the influence of this stored water on direct evaporation from the soil and plant transpiration (together referred to as evapotranspiration) can be quantified. The maximum amount of water available to plants depends not only on soil properties, but also on plant rooting depth. Plant physiologists have measured rooting depths for the major classes of vegetation so that, given vegetation type and soil maps, the amount of water available to the plants for growth and transpiration can be estimated. Depth to groundwater must also be known in regions of shallow water table to ascertain whether phreatophytic extraction may be occurring by plant roots.

Table 1 contains an example of a 40-day-long water budget for a corn crop that begins about a month after emergence, during the period when the crop is growing rapidly. The incoming solar radiation column represents the maximum amount of evapotranspiration that could occur if all the solar radiation were used to evaporate water; of course, some radiation is reflected so the actual evapotranspiration is the sum of the transpiration and direct evaporation from the soil, which is approximately one-third of the maximum possible evapotranspiration. The maximum amount of water that can be stored in the rooting zone is 200 mm for this soil, and clearly the corn crop is using water faster than the rainfall is replenishing it, so that at the end of 70 days of growth approximately half of the maximum soil water storage has been used up. At this point the water depletion in the soil will begin to cause the growth rate of the corn to decrease unless there is more rainfall. This buffering capacity of soil is crucial to growing crops in continental climates all over the world.

Measurements of water transport and storage are difficult and expensive to make, so they can only be done at a few sites under a few conditions. Models that capture the fundamental conservation and transport principles are therefore essential to applying results of limited SPAC studies to a wider range of conditions than could possibly be measured directly. A wide array (hundreds) of computer models is available for quantifying the role of water in the SPAC and the range of applicability of such models depends on having a minimal, faithful representation of critical factors in each component of the SPAC; namely, of the soil, the plant, and the atmosphere. SPAC models can be divided into three classes: simple, intermediate, and complex.

Simple SPAC models are the easiest to create, generally emphasize the knowledge base of one discipline with a narrowly focused purpose and are the most limited in applicability. For example, the Simple Inverse Yield Model (Morgan et al., 2003), for precision agriculture, and the CERES Maize model (Jones and Kiniry, 1986), for crop yield and water-use prediction, neglect the effect of vegetation roughness and wind on evapotranspiration, reflecting their agricultural origins and limitations in applicability. There is also a simple micrometeorological model of evapotranspiration that omits soil processes, reflecting its atmospheric origins and limited applicability.

Intermediate SPAC models incorporate at least a minimal consideration of key soil, plant, and atmospheric components to provide wide applicability without undue complexity. These intermediate models incorporate atmospheric factors (radiation, wind,

The solar radiation is in units of millimeters per day of evaporation that could occur if all solar radiation were to evaporate water. Vegetative cover increases as the crop grows and crop biomass increases. Soil evaporation tends to decrease as the soil surface dries out after rainfall and as vegetative cover increases; evapotranspiration (transpiration plus soil evaporation) exceeds rainfall so soil water storage is gradually depleted.

temperature, humidity, and precipitation), vegetation factors (plant type, vegetative-cover fraction and height, rooting depth), and soil properties (soil evaporation, root-zone water transport and storage). Examples of Intermediate SPAC models include the Two-Source Energy Balance (TSEB) model (Norman et al., 1995), for remote sensing applications, and the ALEX (Atmosphere–Land EXchange) model (Anderson et al., 2000), for local site-specific studies.

Complex SPAC models incorporate most of the processes known to be important at small (leaf to field) scales and can be applied to a wide range of cover types and climatic conditions. Because they are very detailed, they generally involve a large array of coefficients related to specific plant and soil types. For this reason, complex models are often not well-suited to regional scale applications, where these many parameters need to be defined at all locations. The greatest value of complex SPAC models lies in improving our understanding of key processes and using this knowledge to derive intermediate models with fewer parameters and wider applicability. Thus different, but related, models tend to be used to assess phenomena on different spatial scales.

An example of this use of a complex SPAC model is the derivation of the TSEB and ALEX models from the complex Cupid model (Norman and Campbell, 1983). The Cupid model predicts plant–atmosphere exchanges of carbon, water, and energy in a very detailed mechanistic way, and it requires dozens of species-specific coefficients related to plant physiology. By studying the behavior

of the Cupid model, the ALEX model could be created using only a few carefully chosen physiological coefficients and yet achieve a surprising level of generality compared with its parent, Cupid. Not only does ALEX link growth and water use in a way nearly as fundamental as Cupid, but it does so with a widely used ‘light-use efficiency’ coefficient that is already tabulated for most vegetation types around the world (Norman and Arkebauer, 1991). The result of this process is a robust model suitable for continental-scale applications.

Complex SPAC models have also been used to study the relation between the architecture of vegetation canopies and their remotely sensed signatures from aircraft and satellites. Since remote sensing is the only way to characterize vegetative cover at the regional and continental scales, we must understand how to interpret remotely sensed land observations to accommodate the profound influence of vegetation density on energy and material exchanges in the SPAC. For example, in Table 1, the increased importance of transpiration (and extraction of soil water to great depths by plant roots) over evaporation from the soil surface (water extraction to only a few centimeters of soil depth) is apparent as the vegetation cover increases from 17% to almost 90% during the 40 days of growth.

Determining the level of complexity appropriate for an application depends on the objective of the endeavor; typically, the simplest model that provides adequate results is the model of choice. Our understanding of energy and water flows in the SPAC is sufficiently well developed to extend this knowledge to larger scales, where direct measurements are only rarely, if ever, possible and evaluate implications of human activities on ecosystem health.

Upscaling SPAC observations from plot to regional and global scales

The impact of humans on the global ecosystem has become so profound that extending our understanding of biophysical processes from small fields to large regions is becoming critical for our survival. The extension of process-level understanding of energy and material flows in the SPAC to larger scales imposes a severe constraint that is not present in plot-scale studies; namely, that the allowable input quantities are limited to state variables that can be monitored over large areas. Only a few state variables are routinely measured widely from ground-based networks across the world and thus can be considered generally available for monitoring the SPAC. For example, near-surface weather variables (air temperature, humidity, wind speed and direction, precipitation, and cloud cover), solar radiation, atmospheric carbon dioxide, soil maps, vegetation-type maps, river and stream monitoring, and satellite images are routinely obtained at many locations in many countries of the world. This means that these are the main quantities that can be assumed to be generally available everywhere (not always true, but a reasonable assumption). All other inputs required for SPAC models must be computed from fundamental principles or from quantitative relations derived from validation experiments at small scales. This pursuit has been exceedingly challenging, but systematic research over decades in numerous disciplines has identified many of the critical processes and surface parameters, and integrative computer modeling has synthesized much of this information so that monitoring water transport and storage on continental scales may now be possible.

Fig. 3 gives an example of how information about SPAC functioning can be transferred across spatial and temporal scales, here using the TSEB surface energy balance modeling system to estimate evapotranspiration (ET). From Fig. 3 it is apparent that scaling from the small spatial scale of direct measurements (meters to tens of meters) up to large regions (thousands of kilometers) requires use of numerous remote-sensing systems from aircraft and Unmanned Aerial Vehicles (UAVs) to various satellites with very different characteristics. The goal of monitoring daily ET at field scales over large regions may require fusion of data from multiple sensor systems. For example, field measurements at the plot and flux-tower scale have been used to develop simplified descriptions of turbulent heat, mass and momentum exchange based on land-surface temperature and vegetation cover, surface roughness parameters related to vegetation height, and atmospheric stability conditions derived iteratively with the surface fluxes. Surface variability at these scales can be well-mapped at the meter scale using UAVs and low-flying aircraft, but these monitoring systems are too costly to deploy with the time and space sampling required for regional applications. Instead, the insights collected at these finer scales can be tested with coarser resolution, but more routine, imagery collected by operational satellite systems like Landsat and Sentinel-2 at the 10–30 m spatial scale. However, the 5–18 day revisit intervals of these current medium-resolution satellites may miss critical changes in the land-surface status—for example, due to rainfall, irrigation, rapid onset drought, agricultural management, or phenological changes in the vegetation. This is even more likely in humid regions where cloud cover reduces the temporal frequency of usable imagery in the visible to thermal wave bands. Moderate resolution (500–1000 m) polar orbiting sensors like the Moderate Resolution Imaging Spectroradiometer (MODIS) or Visible Infrared Imaging Radiometer Suite (VIIRS) provide near daily information, but at scales that may average over multiple management units or landcover types in a single pixel. In many cases, fusion of medium and moderate resolution ET image timeseries can better approximate field-scale fluxes at daily timesteps (Xue et al., 2022). Geostationary satellites provide excellent temporal sampling (15 min) and broad spatial coverage (thousands of kilometers) with kilometer sized pixels, and measure diurnal variations in solar radiation and surface temperature, as well as atmospheric profiles of temperature and humidity—all critical drivers of SPAC functioning that can help to improve model estimates at the finer spatial scales as well (Anderson et al., 2019). At the continental and global scales, the diagnostic information from remote sensing models can be used to assess the performance of prognostic SPAC models used in climate and biophysical studies, and to identify processes that may not be well-represented within these more complex modeling systems (Hain et al., 2015).

Fig. 3 Mapping ET from plot to global scales using multi-scale thermal remote sensing data within a TSEB-based energy balance modeling system.

Advancing SPAC research: Integration of earth observations, modeling, and ground measurements

Studies of the SPAC are interdisciplinary (involving research in areas that are not claimed by existing disciplines) and multi-disciplinary (requiring collaboration among scientists from numerous disciplines). For example, to understand the influence of vegetation on weather forecasts involves the following activities: meteorologists study the effect of the surface energy and water exchanges on the lower few thousand meters of the atmosphere called the planetary boundary layer; physiologists characterize the dependence of photosynthesis and stomatal processes on atmospheric and soil environmental factors; soil scientists measure the heat- and water-holding characteristics of the soil as well as carbon-exchange processes; micrometeorologists relate vegetation-canopy characteristics and atmospheric variables to the exchange of heat, mass, and momentum with the atmosphere; and hydrologists consider the runoff characteristics of the soil surface and the recharge of groundwater by percolation. The study of vegetative-canopy architecture, within-canopy processes, and the interaction between remote sensing and vegetative cover are key interdisciplinary areas that are not associated with any particular discipline. These multi- and interdisciplinary boundaries can be formidable obstacles to an integrative or holistic quantification of the SPAC, and because so little is known about interactions across these boundaries it is often easier to justify assumptions than engage the unknown knowledge gap.

The use of data from remote sensing retrievals of multiple surface properties across the electromagnetic spectrum is leading to fundamental advances in modeling flux exchanges in the SPAC. For example, while significant efforts with passive and active microwave remote sensing focused on soil moisture retrieval and accounting for the effects of vegetation (e.g., plant water content) on the soil moisture signal (Dorigo et al., 2010), vegetation water content is now seen as useful information in understanding SPAC processes such as plant stomatal behavior to both atmospheric demand and soil moisture conditions (Konings et al., 2017) and with potential applications in quantifying the terrestrial carbon cycle (Konings et al., 2019). Remote sensing of solar-induced fluorescence (SIF), which is a proxy for photosynthesis, is now available from satellites and is being used for constraining global transpiration estimates from SPAC models and other land surface states and fluxes (Jonard et al., 2020; Pagán et al., 2019). Combining the full spectrum of Earth observations is already being utilized in agronomic applications for crop yield estimation (Guan et al., 2017).

Advances in SPAC research in quantifying ET with remote sensing have led to the development of application tools in water resource management; namely, the OpenET {<https://openetdata.org/>, (Melton et al., 2021) effort in the United States, and in Europe the SEN-ET tool {<https://www.esa-sen4et.org/>, (Guzinski et al., 2020) developed by European Space Agency's Sentinel Application Platform. Future satellite missions from both government and commercial enterprises are likely to greatly advance our capability to model the SPAC (McCabe et al., 2017). Indeed, for ET and plant monitoring, the promise of high resolution daily thermal and multispectral infrared observations in the near future from commercial satellites (<https://www.hydrosat.com/>) could provide information necessary for near-real time monitoring of plant water use and stress and lead to a greater understanding of SPAC dynamics.

Clearly, to make such breakthroughs will also require having significant resources devoted to ground truth SPAC-related data. This involves supporting long-term observational networks used by multiple scientific disciplines, such as the Long-Term Ecological Research network (LTER, Kratz et al., 2003) or the U.S. Department of Agriculture experimental watersheds (Goodrich et al., 2021) and Long-Term Agro-ecosystem Research network (LTAR, Bean et al., 2021), providing continuous and reliable data to assess trends in SPAC processes and to validate remotely sensed retrievals from current and future satellite missions. There also need to be dedicated field campaigns, which use remote sensing to address SPAC-related science questions through intensive sampling that long-term networks are not able to provide. Indeed, much of the initial advances in the application of remote sensing for the SPAC came from such multidisciplinary field experiments. Examples in natural ecosystems include FIFE (Sellers et al., 1988), and BOREAS (Sellers et al., 1997), while in agro-ecosystems examples include MONSOON '90 (Kustas and Goodrich, 1994), JORNEX (Havstad et al., 2000), SGP97 (Kustas et al., 2001), SMACEX (Kustas et al., 2005), BEAREX08 (Evelt et al., 2012), and GRAPEX (Kustas et al., 2018).

A recent paper by Durand et al. (2021) provides recommendations on how to better make use of Earth observations to advance hydrologic science. These same recommendations are relevant to advancing SPAC research. They include integrating multi-sensor data over the full electromagnetic spectrum, leveraging commercial satellite observations, and employing not only processed-based models but incorporating data assimilation, making use of cloud computing resources, and incorporating machine learning techniques. The future in advancing SPAC research will be strongly tied to the integration of spatial and temporal information from Earth observations as this is the only means of bridging both spatial and temporal scales from plant level processes up to the global scale.

Abstract

The Penman-Monteith is an elegant, physical expression of the process that water vapor follows when transported from inside the leaf of a plant into the atmospheric boundary layer above. The original Penman combination equation (1948) combined the energy input of radiation from the sun and atmosphere with convective transport of temperature and humidity from the vegetation surface. The Penman-Monteith formulation (1965) included resistance terms for bulk stomates and aerodynamic transport. The equation has gained popularity through its use in estimating reference ET from a grassed surface that is then transformed into ET for specific crops through the crop coefficient.

Key points

- The Penman-Monteith (PM) evapotranspiration (ET) equation estimates the rate of total evaporation and transpiration from the earth's surface
- The PM equation uses commonly measured weather data (solar radiation, air temperature, vapor content, and wind speed)
- The PM equation is derived from a surface energy balance combined with convective transport terms for heat and vapor
- The PM equation is most commonly applied as a reference crop ET equation, for example, for grass and alfalfa surfaces, where assumptions of the equation that surface temperature is near air temperature apply

Introduction

The Penman-Monteith (PM) evapotranspiration (ET) equation (Monteith, 1965) estimates the rate of total evaporation (E) and transpiration (T) from the earth's surface using commonly measured weather data (solar radiation, air temperature, vapor content, and wind speed). The PM equation follows a single-layer or "big leaf" approach, where single surface resistance and single aerodynamic resistance terms represent the transport properties of the vegetated surface. The PM procedure provides scientists, engineers, and managers with the ability to evaluate effects of modifications to cultural practices and crop variety improvements on ET, such as increased plant height, increased or reduced leaf size or density, reduced row spacing, reduced stomatal conductance, etc., by varying these parameters in the calculation algorithms. The PM method is useful in providing direction in determining changes in crop coefficients under new cropping conditions. Determination of crop coefficients is an expensive and time-consuming process, as it requires additional lysimeter or micrometeorological studies.

The PM equation has the form:

$$E \text{ or } ET = \frac{\Delta(R_n - G) + \rho_a c_p (e_s - e_a)/r_a}{\left(\Delta + \gamma \left(1 + \frac{r_s}{r_a}\right)\right) \lambda \rho_w} \quad (1)$$

where Δ is the slope of the saturation vapor pressure vs. temperature curve, R_n is the net radiation flux at the surface, G is the sensible heat exchange from the surface to the soil (positive if the soil is warming), ρ_a is air density, c_p is specific heat of dry air, e_s is the saturation vapor pressure of the air at some height above the surface, e_a is the actual vapor pressure of the air, r_a is aerodynamic resistance to turbulent heat and/or vapor transfer from the surface to some z height above the surface, γ is the psychrometric constant (defined later), r_s is a bulk surface resistance that describes the resistance to flow of water vapor from inside the leaf, vegetation canopy or soil to outside the surface, λ is the latent heat of vaporization, defined as the energy required to convert a mass of liquid water into vapor (having typical units of J kg^{-1}), and ρ_w is density of liquid water. All parameter units in (1) must cancel so that the remaining units for E or ET (depending on application to E from soil or ET from soil and vegetation) are presented as L T^{-1} , for example, mm h^{-1} or mm d^{-1} .

Surface resistance r_s may represent the resistance to vapor flow through plant leaf stomates, or resistance to vapor flow within soil to the soil surface or both in combination. For a wet (saturated) surface, r_s is by definition zero. When r_s is zero, Eq. (1) reverts to the original Penman equation.

Derivation of the Penman-Monteith equation

It is useful to review the derivation of the PM equation to understand how and why it functions. There are two fundamental approaches to estimate E (or ET). These are the surface energy balance equation and the aerodynamic equation. Each equation uses a different approach and each has difficulties for solution when using typical weather data comprised of solar radiation, air temperature, vapor pressure, and wind speed. Penman (1948) combined these two approaches into the so-called combination or Penman equation that could be solved using standard weather data only. Monteith (1965) improved on the Penman (1948) equation by including a surface resistance term and a more rigorous term for aerodynamic transfer.

The surface energy balance equation relates to the various ways in which net radiation energy from the sun and atmosphere is transformed at the surface into outputs of energy in the form of non-radiative parameters. The vertical energy balance at the surface is the sum of sensible heat flux to or from the air and to or from the soil, along with latent heat flux, net radiation and other miscellaneous fluxes. The major components of the vertical energy balance are expressed as:

$$R_n = G + \lambda E + H \quad (2)$$

where λE is the latent heat flux (positive during evaporation) and H is the sensible heat exchange from the surface to air (positive if the air is warming). In Eq. (2), E (or ET) is expressed in terms of the energy required to convert the amount of liquid evaporated into vapor by multiplying by λ . The miscellaneous terms involved in the surface energy balance, such as heat storage within foliage, photosynthesis and respiration are generally insignificant relative to magnitudes of R_n , λE , H and G , and are commonly neglected. Under some conditions, change in heat storage in a canopy may need attention, especially in forest canopies. If R_n and sensible heat flux densities H and G can be measured or estimated reliably, then the latent heat flux density, λE , can be computed from Eq. (2).

$$\lambda E = R_n - G - H \quad (3)$$

The challenge to the solution of Eq. (3) using standard weather data is in solving for H . The traditional aerodynamic expression H is:

$$H = \frac{\rho c_p (T_o - T_a)}{r_{ah}} \quad (4)$$

where T_o is surface temperature, T_a is air temperature and r_{ah} is the aerodynamic resistance to heat transfer between some mean height within the surface to some height a few m above the surface. Generally, r_{ah} is assumed equal to r_a of Eq. (1).

Eq. (4) is analogous to Ohm's law for electrical current flow, where T_o and T_a are equivalent to voltages or potentials, r_{ah} is equivalent to an electrical resistor, and H is analogous to current. Thus, the equation behaves as a linear electrical circuit, so that if the difference between T_o and T_a is doubled, H will double. If resistance r_{ah} is halved (through a doubling of wind speed), then H will double.

The challenge of Eq. (4), and therefore of Eq. (3), is in obtaining surface temperature T_o . T_o can be measured using infrared thermometers, if surface emissivity is known, or it can be measured using a fine-thermocouple or other temperature sensor placed just beneath the surface skin. However, these measurements are not common due to the high operational and maintenance requirements of the instruments and difficulty in transfer of measured values to other locations and surface conditions, even those nearby.

The traditional equation for r_{ah} (and r_a) is:

$$r_{ah} = \frac{\left(\ln \left(\frac{z_u - d}{z_{om}} \right) - \psi_m \right) \left(\ln \left(\frac{z_T - d}{z_{oh}} \right) - \psi_h \right)}{K^2 u_z} \quad (5)$$

where z_u is the height above the ground surface for the wind speed measurement, d is the zero plane displacement of the logarithmic wind profile, z_{om} is a roughness length governing the transfer of momentum from the surface, ψ_m is a correction factor for momentum transfer to account for buoyant instability or stability of the boundary layer, z_T is the height of the air temperature measurement above the ground surface, z_{oh} is an assumed roughness length governing the transfer of sensible heat from the surface, ψ_h is a correction factor for sensible heat transfer to account for instability or stability of the boundary layer, k is the von-karman constant (0.41), and u_z is the wind speed measured at the z_u height. Eq. (5) is sometimes criticized for its use of z_{oh} , commonly expressed as some constant fraction of z_{om} , whereas in reality the ratio of z_{oh}/z_{om} can vary substantially, especially for dry, sparse vegetation (Qualls and Brutsaert, 1996). Other forms of Eq. (5) can be written that rely on differences in T_a and wind speed at two different heights above the surface. Although these forms eliminate the need for z_{oh} , measurement of T_a and wind speed at two heights is not common and it is challenging to produce an unbiased pair of measurements. A variety of studies have investigated effects of foliage density and geometry on apparent bulk roughness of vegetation (see Brutsaert, 1975).

The aerodynamic-based expression for λE is:

$$\lambda E = \frac{\rho c_p (e_o - e_a)}{\gamma (r_{av} + r_s)} \quad (6)$$

where e_o is vapor pressure “inside” the surface, for example inside a leaf stomatal cavity or beneath the soil surface, e_a is vapor pressure of the air at some z height above the ground surface, γ is the psychrometric constant (defined later), r_{av} is aerodynamic resistance to turbulent vapor transfer from the surface to some z height above the surface, and r_s represents any surface resistance to flow of vapor (defined following Eq. 1). Aerodynamic resistance r_{av} is computed exactly as for r_{ah} , i.e., using Eq. (5), except that z_T becomes z_v (height of vapor pressure measurement above the ground), z_{oh} becomes z_{ov} , which is an assumed roughness length governing the transfer of vapor from the surface, and ψ_h becomes ψ_v , a correction factor to account for effect of instability or stability of the boundary layer on vapor flow. Generally, $z_T = z_v$ (air temperature and humidity sensors are usually collocated at the same height), and z_{ov} is assumed equal to z_{oh} and ψ_v is assumed equal to ψ_h . The stability parameters ψ_v , ψ_h and ψ_m can generally be set to zero when calculating ET from well-watered (moist) surfaces because of nearly neutral stability (buoyancy) for those conditions caused by H being close to zero due to conversion of most R_n into λE .

Again, the aerodynamic vapor transfer equation is analogous to Ohm’s law, where e_o and e_a are equivalent to voltages or potentials, r_{av} and r_s are equivalent to electrical resistors *in series*, and λE (vapor flux) is analogous to electrical current.

Vapor pressure of air can be determined from paired measurements of relative humidity and air temperature, which are commonly available or from measurement of dewpoint temperature also commonly available. Vapor pressure inside the soil or plant surface is rarely measured, however, similar to T_o , so that as with Eq. (3), Eq. (6) is challenging to apply in routine practice. Hence the need for the Penman or PM combination equation.

Fig. 1 is a schematic showing the relative locations of resistances r_a (or r_{ah} and r_{av}) and r_s where r_s represents the internal resistance of the soil (if no vegetation) or of the soil, leaves and canopy *in parallel*.

To create the PM equation, one needs to define what is known as the Bowen ratio which is simply the ratio between H and λE . Expanded into the equations for H and λE and written for transfer from *inside* the surface to the air above:

$$\beta = \frac{H}{\lambda E} = \frac{\rho c_p (T_o - T_a) \gamma (r_{av} + r_s)}{\rho c_p (e_o - e_a) (r_{ah})} \quad (7)$$

Cancelling similar terms:

$$\beta = \frac{H}{\lambda E} = \gamma \frac{(T_o - T_a) (r_{av} + r_s)}{(e_o - e_a) (r_{ah})} \quad (8)$$

The energy balance equation can be rearranged and written as:

$$\lambda E = \frac{R_n - G}{1 + \beta} = \frac{R_n - G}{1 + \gamma \frac{(T_o - T_a) (r_{av} + r_s)}{(e_o - e_a) (r_{ah})}} \quad (9)$$

The next step in the derivation of the PM equation is to define the term Δ , which is defined as the slope of the saturation vapor pressure vs. temperature relation. Saturation vapor pressure $e_o(T)$ is a singular function of T and describes the ability of air to hold more vapor as temperature increases. The slope Δ of the $e_o(T)$ vs. T curve can be expressed as a linear approximation for a segment of the saturation curve between two temperatures T_o and T_a :

$$\Delta = \frac{e_o - e_s}{T_o - T_a} \quad (10)$$

where e_o , e_s , T_o and T_a were defined previously. Vapor pressure inside the surface, e_o , is assumed to be saturated and is therefore equivalent to $e_o(T_o)$. e_s is the saturation vapor pressure associated with T_a , so that $e_s = e_o(T_a)$. In practice, Δ is often calculated as the

Fig. 1 Schematic showing linkage between resistance terms in the PM equation relative to the surface and elevation of temperature and humidity measurements. ET, evapotranspiration; e_s , saturation vapor pressure at mean air temperature; e_a , actual vapor pressure of the air; G , heat exchange from surface to soil; H , heat exchange from surface to air; r_a , aerodynamic resistance; r_s , bulk surface resistance; R_n , net radiation flux at the surface; T_a , air temperature; r_{av} , aerodynamic resistance to vapor transfer; r_{ah} , aerodynamic resistance to heat transfer.

slope of $e_o(T)$ vs. T at T_a only, since T_o is usually not known and can be substantially warmer or cooler than T_a . More is discussed on this later.

Using the relationship from Eq. (10) to define $(e_o - e_s)/\Delta = T_o - T_a$ and parsing $(e_o - e_s)$ into an equivalent expression of $(e_o - e_s) = (e_o - e_a) - (e_s - e_a)$ so that $T_o - T_a = [(e_o - e_a) - (e_s - e_a)]/\Delta$, this expression is substituted into Eq. (9) so that:

$$\lambda E = \frac{R_n - G}{1 + \beta} = \frac{R_n - G}{1 + \frac{\gamma}{\Delta} \frac{[(e_o - e_a) - (e_s - e_a)](r_{av} + r_s)}{(e_o - e_a)(r_{ah})}} = \frac{R_n - G}{1 + \frac{\gamma}{\Delta} \left[1 - \frac{(e_s - e_a)}{(e_o - e_a)} \right] \frac{(r_{av} + r_s)}{r_{ah}}} \quad (11)$$

We define one more temporary term, λE_a , following Penman (1948):

$$\lambda E_a = \frac{\rho c_p (e_s - e_a)}{\gamma r_{ah}} \quad (12)$$

where λE_a is similar to Eq. (6), the aerodynamic expression for λE , except that r_s is omitted and $(e_o - e_a)$ is replaced with $(e_s - e_a)$. E_a is a fictitious term that allows the elimination of surface parameters T_o and e_s in the final PM equation. The term $(e_s - e_a)$ is known as the vapor pressure deficit (VPD) of the air, because it represents the difference between the saturation vapor pressure at air temperature ($e_s = e_o(T_a)$) and actual vapor pressure of the air (e_a). Both e_s and e_a can be determined from commonly available humidity and air temperature data measured at some height above the surface, generally 1.5–2 m. Because

$$\frac{e_s - e_a}{e_o - e_a} = \frac{\lambda E_a}{\lambda E} \frac{r_{ah}}{r_{av} + r_s} \quad (13)$$

Then Eq. (11) becomes

$$\lambda E = \frac{R_n - G}{1 + \frac{\gamma}{\Delta} \left[1 - \frac{\lambda E_a}{\lambda E} \frac{r_{ah}}{r_{av} + r_s} \right] \frac{r_{av} + r_s}{r_{ah}}} \quad (14)$$

Rearranging Eq. (14) and setting $r_{av} = r_{ah}$ results in the PM equation:

$$\lambda E = \frac{\Delta (R_n - G) + \gamma \lambda E_a}{\Delta + \gamma \left(1 + \frac{r_s}{r_{ah}} \right)} = \frac{\Delta (R_n - G) + \rho c_p (e_s - e_a)/r_{ah}}{\Delta + \gamma \left(1 + \frac{r_s}{r_{ah}} \right)} \quad (15)$$

where, in Eq. (15), E is expressed in terms of energy, rather than in terms of depth of liquid water as in Eq. (1). The PM equation has the extremely valuable advantage of requiring only commonly available weather data, namely solar radiation (used to calculate R_n), air temperature (used to calculate ρ , e_s and Δ), air humidity (used to calculate e_a and assist with R_n), and wind speed (for r_{ah}).

Parameter G is generally estimated as a function of R_n or by direct measurement and r_s is generally estimated as a function of amount of vegetation or amount of surface wetness, of soil. The PM (and Penman equation where r_s is assumed zero and $1/r_{ah}$ is replaced by a simpler empirical “wind function”) are widely used around the world as standard means to predict E and ET . As discussed later, estimation of Δ from T_a only is mostly valid under well-watered (reference crop) conditions where $T_o \sim T_a$. This was the approach of Penman who developed his combination equation for grass and water surfaces.

Other parameters in the PM equation

The psychrometric constant γ is computed as:

$$\gamma = \frac{c_p P}{\lambda \varepsilon} \quad (16)$$

where, $c_p = 1.013 \text{ kJ kg}^{-1} \text{ K}^{-1}$ for moist air, P is atmospheric air pressure, λ is the latent heat of vaporization in kJ kg^{-1} , and $\varepsilon = 0.622$ is the ratio of molecular weights of water vapor to air. For P in kPa, γ will have units of $\text{kPa } ^\circ\text{C}^{-1}$. Mean atmospheric air pressure, P , can be routinely computed as a function of surface elevation using the ideal gas law (Allen et al., 1998) as:

$$P = P_{os} \left(\frac{T_{os} - \alpha_a (\text{elev} - \text{elev}_{os})}{T_{os}} \right)^{g/(\alpha_a R)} \quad P = P_{os} \left(\frac{T_{os} - \alpha (\text{elev} - \text{elev}_{os})}{T_{os}} \right)^{\frac{g}{(\alpha_a R)}} \quad (17)$$

where P_{os} and T_{os} are standard atmospheric pressure in kPa and absolute temperature in K at elevation elev_{os} , and elev is elevation of the ground surface above mean sea level, α_a is the assumed constant adiabatic lapse rate, normally taken as 0.0065 K m^{-1} for saturated air or sometimes as 0.01 K m^{-1} for non-saturated air, g is gravitational acceleration, 9.807 m s^{-2} and R is the specific gas constant for dry air, $287.0 \text{ J kg}^{-1} \text{ K}^{-1}$. Values for P_{os} , T_{os} and elev_{os} are commonly taken for the standard atmosphere at sea level, which are 101.3 kPa, 288 K, and 0 m, respectively. Eq. (17) is relatively insensitive to the value of α_a for elevations up to 3000 m.

Air density, ρ , can be computed as

$$\rho = \frac{1000 P}{T_v R} \quad (18)$$

where P is in kPa, R is $287.0 \text{ J kg}^{-1} \text{ K}^{-1}$ and T_v is virtual temperature, in K. T_v can be computed as:

$$T_v = \frac{T}{1 - 0.378 \frac{e_a}{P}} \quad (19)$$

where T is air temperature in K and e_a is mean vapor pressure of the air, kPa.

Latent heat of vaporization, λ , in MJ kg^{-1} can be computed as:

$$\lambda = 2.501 - 0.002361 T \quad \lambda = 2.501 - 0.002361 T \quad (20)$$

where T is mean air temperature in $^\circ\text{C}$. If available, mean surface temperature or wet bulb temperature can be used to compute the value of λ which better represents conditions at the evaporating surface.

The PM equation can be applied for short periods of 1 h or less, and in fact is intended to represent nearly instantaneous fluxes of ET . However, the equation has traditionally been applied for daily and longer (up to 1 month) calculation timesteps due to paucity of weather data. For daily and longer timesteps, e_s in the PM should be computed as:

$$e_s = \frac{e^o(T_{max}) + e^o(T_{min})}{2} \quad (21)$$

where T_{max} and T_{min} are maximum and minimum daily air temperature for the period and e^o is the saturation vapor pressure function. Actual vapor pressure of the air, e_a , can be computed from relative humidity data, from wet-bulb and dry-bulb psychrometer data, or from dewpoint temperature measurements:

$$e_a = e^o(T_d) \quad (22)$$

where T_d is mean daily or early morning dewpoint temperature.

Aerodynamic and surface parameters

When used to estimate ET from dense vegetation, aerodynamic resistance in PM can be calculated using parameters for d , z_{om} , and z_{oh} determined as a function of vegetation height:

$$d = 0.67 H \quad (23)$$

$$z_{om} = 0.12 H \quad (24)$$

$$z_{oh} \approx 0.1 z_{om} \quad (25)$$

where z_{om} , z_{oh} , d , and mean plant height, H , are in m. For bare soils, common values for z_{om} range from 0.00001 m for mud flats to 0.005 m for smooth soil to 0.01 m or higher for very roughly ploughed soil.

Parameterization of surface resistance

The bulk surface resistance r_s for a crop is an integration of effects of transpiration from various locations within the vegetation and contributions from soil evaporation, along with transfers of radiation and sensible heat within the canopy. Simple approaches determine soil evaporation indirectly by estimating the distribution of net radiation below and between a plant canopy having partial ground cover. For crops that completely shade the ground, total surface resistance can be computed following Grant (1975) where surface resistances from soil and vegetation are added in parallel according to leaf area and radiation extinction coefficients. For an immature row crop or natural vegetation having exposed bare soil between plant rows and incomplete wetting of the soil surface during irrigation, r_s can be expressed as an extension of Grant's approach through combination of various surface resistances acting in parallel. The combination is made according to the fractions of surface C represented by each parallel resistance component (Fig. 2):

$$\frac{1}{r_s} = \frac{C (1 - K_r^{LAI/C})}{r_{sc}} + K_r^{LAI/C} \left(\frac{C_{sW}}{r_{ssw}} + \frac{C_{sD}}{r_{ssd}} \right) + \frac{C_{eW}}{r_{sseW}} + \frac{C_{eD}}{r_{sseD}} \quad (26)$$

where C is the effective fraction of ground shaded by vegetation and is computed as a function of sun angle, row height and width, leaf density, and row orientation, and C_{sW} , C_{sD} , C_{eW} , and C_{eD} are the fractions of the soil surface that are shaded and wet, shaded and dry, sunlit and wet, and sunlit and dry ($C_{sW} + C_{sD} + C_{eW} + C_{eD} = 1$ and $C_{sW} + C_{sD} = C$). Resistance r_{sc} is the surface resistance of the canopy, r_{ssw} is the surface resistance of wet, shaded soil, r_{ssd} is the surface resistance of dry, shaded soil, r_{sseW} is the surface resistance of wet, sunlit soil, and r_{sseD} is the surface resistance of dry, sunlit soil. Parameter K_r is a radiation extinction coefficient for the vegetation canopy having a value of approximately 0.7 (Grant, 1975) and where LAI is leaf area index defined as the aggregated surface area (one-side) of leaves per unit of ground surface area.

Thompson et al. (1981) computed C as $LAI/4$. Brisson (1996) applied separate PM equations for evaporation and transpiration and then recoupled them, similar to the procedure for multi-layer ET models. For sun angles other than directly overhead, C can be estimated for a row crop following Allen et al. (1998) as:

$$C = \frac{W + H |\sin(\eta + \beta)| \tan \theta_z}{S} \quad (27)$$

where H is mean plant height, θ_z is the solar zenith angle ($0 = \text{nadir (overhead)}$), η is the sun azimuth angle (in the northern hemisphere, $\eta = 0$ when sun is due south in the northern hemisphere, η is negative when sun is east of south and η is positive when

Fig. 2 Schematic showing breakdown and definition of surface resistances for soil when vegetation is at partial cover. r_a , aerodynamic resistance; r_{sc} , surface resistance for the vegetation cover; r_{ssw} , surface resistance of wet, shaded soil; r_{ssd} , surface resistance of dry, shaded soil; r_{sseW} , surface resistance of wet, sunlit soil; r_{sseD} , surface resistance of dry, sunlit soil; C_{sD} , fraction of the soil surface that is shaded and dry; C_{sW} , fraction of the soil surface that is shaded and wet; C_{eW} , fraction of the soil surface that is sunlit and wet; C_{eD} , fraction of the soil surface that is sunlit and dry.

sun is west of south), and β is the row orientation relative to north ($\beta = 0$ for north-south orientation, $\beta = 90^\circ$ for east-west row orientation), W is row width and S is row spacing. Eq. (27) presumes a nearly rectangular row shape of height H and width W and has an upper limit of $C = 1$. In some situations, W may not be measured or available, but an estimate of LAI may be available. In this case, C may be approximated during incomplete row closure as:

$$C = \frac{LAI}{LAI_C} + \frac{H}{S} |\sin(\eta + \beta)| \tan \theta_z \quad (28)$$

where LAI_C is the LAI at complete row closure and shading of the ground. The value for C and, subsequently, for r_s changes with time of day and interacts with R_n , G , wind speed and temperature. For 24-h computation time steps, an average daily value for C is determined for computing soil moisture balances for shaded and unshaded soil. An average daily value for C for east-west rows can be determined by weighting Eq. (27) for sunlight intensity and integrating between the limits of sunrise and sunset. For north-south row orientation, all soil is sunlit and shaded at various times of the day.

Surface resistance, r_{sc} , for densely growing vegetation is often computed in the “single-layer” PM as a function of leaf area by assuming all leaves function as resistors in parallel:

$$r_{sc} = \frac{r_l}{LAI_{eff}} \quad (29)$$

where r_l is the bulk stomatal (or surface) resistance of the vegetation per unit LAI ($s\ m^{-1}$) and LAI_{eff} is the effective LAI contributing to ET. Parameter r_l is the inverse of g_l , the stomatal conductance per unit leaf area. The value of r_l has been taken as $100\ s\ m^{-1}$ for many well-watered agricultural crops (Monteith, 1965; Allen et al., 1989) when calculations are made on a 24-h basis. When ET calculations are made on an hourly or shorter basis, r_l for agricultural crops has a value of about $70\text{--}80\ s\ m^{-1}$ (Allen et al., 2006). The value for r_l increases with environmental stresses including soil moisture deficit.

Surface resistance, r_{sc} , plays an important role in controlling the flux of transpiration from plants into the atmosphere and must be accurately predicted for routine application of the PM and multilayer ET models. r_{sc} represents the ET-averaged daily resistance for 24-h calculation time steps or the mean canopy resistance for hourly time steps for a fully developed canopy. Algorithms are used to modify r_{sc} as leaf area (LAI) and environmental parameters change. General, simple environmental stomatal regulation algorithms have been proposed by several authors, including Lecina et al. (2003) where bulk surface resistance is expressed in terms of multiplicative products of linear functions of solar radiation, air temperature, vapor pressure deficit and soil water deficit.

Soil resistance is generally assumed to increase with drying of soil. Exponential functions describe the process relatively well. A moisture-based soil resistance function that describes experimental data from a Portneuf silt loam soil near Kimberly, Idaho is:

$$r_{ss} = 2000e^{-5x_s} \quad (30)$$

where x_s is the remaining proportion of water in the evaporating layer of the soil surface and e is the natural number. x_s is computed as $x_s = W_{ei}/W_{emax}$, where W_{ei} is the total evaporable moisture near the soil surface on day i and W_{emax} represents the upper limit of evaporable water. A daily or more frequent water balance of the C_{sw} , C_{SD} , C_{EW} , and C_{ED} fractions of the soil surface layer need to be conducted to predict x_s , and thus r_{ss} , for each surface fraction. The E from each fraction is predicted in some proportion to ratio of the inverse of r_{ss} for that fraction to the total bulk r_s for the soil-canopy complex as in Eq. (26). The soil surface layer is typically presumed to be $0.1\text{--}0.15\ m$ thick (Allen et al., 1998). Eq. (30) predicts values for r_{ss} ranging from about $15\ s\ m^{-1}$ directly after wetting to about $2000\ s\ m^{-1}$ for a relatively dry surface soil layer. Or and Lehmann (2019) developed a soil-dependent evaporative characteristic length defines an active surface evaporative capacitor depth below which soil water is sheltered from capillary pull to the evaporating surface. They tested and applied their model globally.

Multi-layer ET models

The PM equation is basically a single layer model where the resistances for vegetation and soil are assumed to reside in parallel, i.e., there are no intermediate aerodynamic or convective resistances separating them or within them. More complicated multi-layer ET models have been employed that contain sophisticated parameter algorithms, intermediate resistances, and relatively complex calculation mechanisms than PM. Multi-layer models decompose the computation of r_s , r_{sc} , and r_a for discrete layers within the vegetation canopy (e.g., Wallace (1996), and Colaizzi et al. (2012)). Because of their increased complexity, multi-layer models can provide more capability and flexibility in predicting ET under variable cropping and weather conditions without the need for calibration, depending on the physical basis of internal mechanisms. Estimated ET may be more accurate than the PM, especially for short time steps (hourly). On the other hand, these models sometimes require substantial calibration of empirical coefficients internal to the model and may use questionable assumptions regarding values for canopy and soil temperature used in estimating spatial distribution of R_n as discussed later.

Net radiation

Net radiation, R_n , can be measured using a net radiometer that measures downward and upward fluxes of short-wave and long-wave radiation. The surface beneath the net radiometer must be very similar in wetness and vegetation type and amount to that being predicted in the PM equation. In many situations, R_n data is not available for a specific surface or condition, and therefore must be

estimated from solar radiation data, air temperature, and possibly vapor pressure. R_n for row crops is often calculated by separately considering the reflectances (albedo) for soil and vegetation. When calculated, the general formula for R_n is:

$$R_n = (1 - \alpha)R_s + R_{nl}R_n = (1 - \alpha)R_s + R_{nl} \quad (31)$$

where α is the albedo of the surface, representing the crop-soil mixture, R_s is incoming short-wave radiation (measured by a pyranometer), and R_{nl} is net (incoming-outgoing) long-wave radiation. R_{nl} is commonly estimated from air temperature and humidity data from a local weather station (Allen et al., 1998), however R_{nl} should be based partly on T_o of the surface that emits the long-wave thermal radiation:

$$R_{nl} = R_{L\downarrow} - R_{L\uparrow} - (1 - \epsilon_o)R_{L\downarrow} = \epsilon_o\epsilon_a\sigma T_a^4 - \epsilon_o\sigma T_o^4 \quad (32)$$

where $R_{L\downarrow}$ is incoming long-wave radiation from the atmosphere, $R_{L\uparrow}$ is outgoing (emitted) long-wave radiation from the surface having temperature T_o (in Kelvin), ϵ_o is broad-spectrum thermal emissivity of the surface, generally between 0.95 and 0.99 and ϵ_a is broad-spectrum thermal emissivity of the near surface atmosphere. The $(1 - \epsilon_o) R_{L\downarrow}$ term represents the fraction of incoming long-wave radiation reflected from the surface. T_a used in the Stephen-Boltzman expression in Eq. (32) represents the temperature of the lower near surface atmosphere that is responsible for emitting the majority of thermal radiation to the surface. One can note that differences in surface temperature, T_o , between wet, evaporating and dry surfaces can be as much as 30 K. Those differences in T_o can cause differences in emitted long-wave radiation from the surface and consequently R_n to be as large as 100 W m^{-2} between the two conditions.

A general formula for α of a crop-soil mixture used by Thompson et al. (1981) is:

$$\alpha = C\alpha_c + (1 - C)\alpha_s \quad (33)$$

where α_c is plant albedo, α_s is soil albedo and C = relative fraction of vegetation cover (defined previously) that considers effects of sun angle. Plant albedo can be computed by choosing typical values at the key growth stages. For example, Vanderkimpfen (1991) found values of α_c to be 0.25, 0.23, 0.23 and 0.30 for beans at Kimberly at emergence, effective cover, ripening and harvest. Values were 0.25, 0.15, 0.15 and 0.35 for wheat for the same stages due to the more vertical leaf structure for wheat and penetration of radiation into the canopy. For overcast conditions where most shortwave radiation is diffuse, the value for α_c increases, often to about 0.35.

Soil albedo in (32) can be computed as a composite of wet soil and dry soil albedo:

$$\alpha_s = \frac{\alpha_{sM} C_{eW} + \alpha_{sD} C_{eD}}{C_{eW} + C_{eD}} \quad (34)$$

where α_{sM} is albedo of moist soil and α_{sD} is albedo of dry soil. The albedo of a moist, drying soil can be assumed to vary linearly with water content between the value for a fully wet soil and a fully dry soil over a given drying period:

$$\alpha_{sM} = \alpha_{sW} + (\alpha_{sD} - \alpha_{sW})(1 - x_{skin}) \quad (35)$$

where α_{sW} is albedo of wet soil and x_{skin} is the fraction of remaining water in the soil skin (top $\sim 1 \text{ cm}$). Example values for α_{sW} and α_{sD} for the Portneuf silt loam near Kimberly, Idaho (Vanderkimpfen, 1991) are $\alpha_{sW} = 0.10$ – 0.20 and $\alpha_{sD} = 0.35$.

Soil heat flux

The magnitude of soil heat storage or release can be significant over a few hours, but is usually small from day to day because heat stored early in the day as soil warms is lost late in the day and at night as the soil cools. For application of PM to short-periods, e.g., using hourly data, measurements or estimates for G are required.

One method commonly used in research is the use of heat flux plates installed at shallow depths below the soil surface. (e.g., at 0.01 m). Installation and measurement with heat flux plates is described by Campbell Scientific Inc (1999). Measurements by soil heat flux plates, G_{zs} at some depth z_s are adjusted to represent G at the soil surface by incorporating the change in heat storage between the soil surface and heat flux plate:

$$G = G_{zs} + C_s \int_0^{z_s} \frac{\partial T_s}{\partial t} dz \quad (36)$$

where $\partial T_s / \partial t$ is the change in temperature with time within the z_s thick layer above the heat flux plate. Temperature is usually measured with thermocouples or buriable thermistors.

Soil heat flux density for dense, short vegetation such as for grass, wheat or alfalfa can be approximated during daylight periods as (Choudhury et al., 1987):

$$G = 0.4 e^{-0.5 LAI} R_n \quad (37)$$

where e is the natural number and G has the same units as R_n . Eq. (37) predicts $G = 0.1 R_n$ for an $LAI = 2.8$, which is typical for clipped grass. A very small fraction of G/R_n (0.036) has been adopted during daylight, even for full-cover alfalfa (0.04) and Verma et al. (1986) used 0.036 for a deciduous forest. For $LAI = 0$ (i.e., bare soil), Eq. (36) estimates $G/R_n = 0.4$.

For nighttime under grass forage, Allen et al. (1998) recommend $G = 0.5 R_n$ for grass and 0.2 for full-cover alfalfa. During late evening and early morning, values for G will be negative as heat flows upward toward the surface. In these reported ratios, the effects of seasonal variations are not addressed. The seasonal lag of soil temperature behind solar radiation can be expected to produce higher ratios.

Application of the PM equation

Besides direct application of the PM equation to a complex surface of soil and vegetation (Ortega-Farias et al., 2006; Leuning et al., 2008) or to soil only, the equation has been widely used to represent ET from a reference vegetation crop for use in irrigation management (e.g., Pruitt and Doorenbos, 1977; Allen et al., 1998, 2006; ASCE, 2016). The reference crop ET (ET_o) represents ET from either a cool season clipped grass or a tall full-cover alfalfa crop, depending on the parameters specified for aerodynamic and surface resistances (Allen et al., 1989; ASCE, 2016).

When the PM equation is used as an ET reference, actual ET for a soil or soil-vegetation surface is computed by multiplying ET_o by a crop coefficient, K_c , where K_c represents the ratio of actual ET to ET_o . The value for K_c of soil is varied according to the moisture level of the soil. Detailed information and values for K_c for many crops are included in Allen et al. (1998).

Fig. 3 shows a comparison of hourly ET estimated by the ASCE version of the PM equation and ET measured by a precision weighing lysimeter (essentially a large flower pot suspended below ground via mechanical balances). The PM estimates, based on measured solar radiation, air temperature, humidity, and wind speed, agreed very well with field measurements. Results are not always this good, however, and depend on the representativeness of values for roughness and for surface resistance. Sensitivity of the PM to each of the four weather components depends on climate and the relative strengths of each component relative to the others (Irmak et al., 2006; Estévez et al., 2009).

Limitations to applying the PM equation

The PM equation functions best when applied as a reference ET equation that represents a near maximum ET from vegetated surfaces. This is because when ET is near maximum, then H , from Eq. (3) is nearly zero so that T_o is close in value to T_a . When this occurs, Δ in Eq. (1) can be estimated accurately from T_a only. In addition, when $T_o \sim T_a$, R_n can be estimated correctly using only T_a . However, when ET flux from a surface is less than a reference or near maximum rate, then H becomes increasingly large and, from Eq. (4), $T_o > T_a$. This condition then requires the following: (i) Calculation of Δ requires the use of both T_o and T_a (Eq. 10); (ii) the R_{nl} calculation (Eq. 32) requires an estimate for surface temperature T_o rather than assuming $T_o \sim T_a$; (iii) the value for G is often larger than when H is nearly 0 and should consider the magnitude of T_o ; and (iv) numerical correction to r_{ah} should be performed when T_o is substantially different from T_a using near-surface boundary layer stability corrections (Eq. 5).

Because T_o is not generally measured, when T_o is substantially different from T_a , it must be estimated by iteratively calculating its value using the four components of the energy balance (Eq. 3). This requires iterative and consecutive recalculation for

Fig. 3 Comparison between evapotranspiration (ET) during hourly periods predicted by the Penman–Monteith (PM) equation (using parameters from the American Society of Civil Engineers (ASCE)) and ET measured by a precision-weighing lysimeter.

(i) R_n (Eqs. 31 and 32); (ii) G (Eq. 36) or an equation based on T_o (ASCE, 2016); (iii) λE (Eq. 6); (iv) T_o using an inversion of Eq. (4) with H from an inversion of Eq. (3); (v) r_{ah} from Eq. (5), using boundary layer stability corrections that are based on H ; and (vi) Δ from Eq. (10). Iteration proceeds until a value for T_o has stabilized. When this occurs, then appropriate values for Δ , R_n , r_{ah} and G have been calculated and the iterated values can be used in PM (Eq. 1) so that accuracy of the equation is preserved. Ironically, when the above iterative solution, known as the AFIB approach (aerodynamic fluxes via iterative solution of the energy balance) from ASCE (2016), is applied, the need for the PM application “evaporates,” because λE has already been calculated from Eq. (6). Deployment of the AFIB solutions for T_o , Δ , R_n , r_{ah} and G into PM (Eq. 1) produces equivalent estimates to Eq. (6). As an example, applying PM (Eq. 1) in southern Idaho over dry rangeland conditions and using only T_a for the PM equation components overstates ET by about 30 W m^{-2} or 20% (ASCE, 2016, Table 11-6).

The PM method has been applied successfully using parameterization of R_n , r_{ah} and r_s parameters from satellite imagery (Consoli et al., 2006; Ciraolo et al., 2012; D’Urso et al., 2010, 2021). The utility of using remote sensing imagery is that spatial variation in LAI, albedo, plant density and maturity can be captured at a within-field parcel scale. Local calibration of parameters may be required.

The PM equation has even been applied to estimate ET in greenhouses (Seginer, 2002; Yan et al., 2019). However, the aerodynamic terms and potentially the net radiation terms in the PM may deviate substantially from equilibrium boundary layer conditions assumed during development of the PM.

Applying PM with gridded weather forecast data sets

Gridded weather data from weather forecast models are commonly used for ET, because they provide the necessary information on a spatial scale to estimate ET using PM, including the calculation of reference ET, ET_o . Data common to gridded weather data sets include solar radiation or sky cover, near-surface air temperature, humidity, and wind speed. ET_o is a vital parameter in agricultural water management and for most remote sensing (RS) approaches to ET estimation. However, a concern with using gridded data is that, in dry regions, the gridded data represent ambient weather conditions where T and humidity profiles extending above the surface have elevated T and lower e than what occurs over a well-watered “reference” surface as previously described. The standardized PM for computing ET_o requires that the near-surface profiles for air temperature, humidity, and wind speed are in equilibrium with the actively transpiring well-watered surface represented by ET_o . This is a basic requirement of applying the PM equation (ASCE, 2016; Blankenau et al., 2020; Paredes et al., 2018). As a consequence, if gridded weather data fail to represent the near-surface air properties of well-watered agricultural areas, then ET_o will tend to be overstated.

Current applications of the PM equation as a grass-based ET_o estimate include the global WaPOR Daily Reference Evapotranspiration 2.0 produced by the UN-FAO (2020), by the FAO AQUASTAT modeling (UN-FAO, 2021) and for the USA as part of the Climate Engine (Huntington et al., 2017).

Empirical approaches have been suggested for adjusting T and e data to better reflect well-watered reference conditions prior to ingestion into the PM (Jensen et al., 1997; ASCE, 2016). In addition, theoretical approaches have been offered that are based on boundary layer profile theory (Allen et al., 2021).

Conclusion

The Penman-Monteith evapotranspiration model was developed in 1965 to enable estimation of ET from a wide range of vegetation using only weather parameters collected in the air above the vegetation surface. This eliminated the need to measure surface temperature. The PM method has found most application to a well-watered grass reference surface where the ET estimate represents near maximum ET resulting from observed weather. The reference ET estimate is used as a basis to estimate ET from a range of vegetation and crop types.

Abstract

Infiltration is the flow of water across the ground surface into the soil. This process provides a critical link between surface hydrologic processes and subsurface soil and groundwater systems. While this flux occurs at the ground surface, full understanding of infiltration requires the energy status of water in the shallow subsurface, as well as insight into how these conditions change as infiltration continues. This article explains the basic concepts, and provides the foundational equations, needed to understand infiltration. These insights apply both to those who have a primary interest in infiltration as a mechanism that removes water from the surface as well as for those who are interested in the delivery of water to the soil.

Key points

- Two perspectives of infiltration: rate that water leaves above-ground systems and rate that water adds to the subsurface
- Infiltration described with Darcy's law.
- Equations presented for water infiltration across moisture gradients and from ponded surfaces.

Two perspectives on infiltration

Infiltration refers to the flux of water across the ground surface into the soil below. This simple process depends on many of the most complex aspects of water flow including the dependences of water content on water pressure and of hydraulic conductivity on water content and the significant storage capacity associated with changes in water content with time. Because it relates to the connection between two physical realms – above and below ground – infiltration also provides useful insight into the ways that a single phenomenon can be viewed differently from different practical and scientific perspectives. As an example, two views are presented here: infiltration as a control on the rate that water will leave above-ground systems and as a control on the rate at which water can be added to the subsurface. The latter is the traditional focus of soil scientists while the former informs hydrology, global circulation models, and many engineering disciplines.

For many practical applications and scientific fields, infiltration is a hydrologic process that removes water from the domain of interest. For example, if the objective is to predict flooding during a rainstorm, then infiltration determines how much of the rainwater will contribute to runoff and flooding. From this perspective, the most important system characteristic is the infiltration capacity. Namely, given the soil type, initial conditions, and water application rate at the soil surface, the infiltration capacity determines the fraction of the supplied water that infiltrates across the surface interface as a function of time.

Steady-state infiltration with minimal surface ponding

If there are no other impediments to flow in the subsurface (an impermeable layer or a shallow water table), the soil surface can admit infiltration at a rate close to its saturated hydraulic conductivity, (K_s [LT^{-1}]), continuously with no ponding. The qualification that infiltration is often less than K_s is due to the impacts of entrapped air in the soil, which can reduce the steady infiltration rate to between $K_s/3$ and $K_s/2$. This steady infiltration rate, q follows directly from Darcy's Law at the surface:

$$q = -K_s \frac{d(z + \varphi)}{dz} \quad (1)$$

where z is depth and φ is the pressure head. Specifically, the infiltration flux (q [LT^{-1}]) is equal to the saturated hydraulic conductivity such that flow is driven only by gravity. As a result, the pressure head is zero everywhere and there is no ponding of water above the ground surface. It follows from this that any applied flux that is less than K_s will not result in ponding, either. Rather, the soil water content will increase to a level at which the hydraulic conductivity at that water content is equal to the applied flux. The water content will again be constant with depth (assuming a homogeneous subsurface) and the pressure head of the water will be less than zero.

An agricultural perspective – delivering water to the subsurface

In agriculture-related fields, there is often interest in determining how much water can be supplied to the subsurface, with the clearest example being planning for irrigation. As explained above, water that is supplied at a rate that is equal to or less than K_s will not result in ponding. Therefore, regardless of the initial water content, the infiltration rate will be equal to the rate at which water is applied. The cumulative infiltration (I [L]) will equal the infiltration rate multiplied by the time for which water is applied. This would apply to spray or sprinkler irrigation that is maintained at a rate less than K_s , for example.

Transient infiltration

Because the hydraulic conductivity increases with increasing water content, it may seem counter-intuitive that a drier soil can admit infiltration at a faster rate than a wetter soil. This occurs because of the capillary forces that draw water into the drier soil. The first mathematical model of this influence was provided by [Green and Ampt \(1911\)](#). They consider a wetting front (zone of constant water content with depth extending from the ground surface) that advances due to water supplied at a constant pressure head φ_s [L] at the ground surface ([Fig. 1](#)). They define a pressure head at the wetting front, φ_{wf} [L], which has a value between the initial pressure head, φ_i [L], and φ_s . For any time since the beginning of infiltration, Δt , the cumulative infiltration to that time, I [L], must equal the depth of the wetting front, z_{wf} [L], multiplied by the change in volumetric water content across the wetting front, $\Delta\theta$ [$-$].

$$I = z_{wf} \Delta\theta \quad (2)$$

Darcy's Law can be applied over the entire wetting front at that time. Taking the datum elevation to be the ground surface, the hydraulic head at the wetting front, H_{wf} [L], and the ground surface, H_s [L], respectively, are:

$$H_{wf} = -z_{wf} + \varphi_{wf} \quad (3)$$

Fig. 1 Schematic representation of a wetting front with key variables.

$$H_s = 0 + \varphi_s \quad (4)$$

The infiltration flux, I [LT^{-1}] is then:

$$i = -K(\theta_{wf}) \frac{(0 + \varphi_s) - (-z_{wf} + \varphi_{wf})}{z_{wf}} = -K(\theta_{wf}) \frac{z_{wf} + (\varphi_s - \varphi_{wf})}{z_{wf}} \quad (5)$$

At long times, this states that the infiltration rate approaches the hydraulic conductivity of the medium at the water content above the wetting front. This shows steady state equivalence between conditions for which the rate of water supply or the pressure head of water at the ground surface are defined. However, at early times during the infiltration process, when the depth to the wetting front is relatively small, the difference in the pressure of the water over the wetting front leads to an infiltration rate that is greater than this asymptotic rate. Plainly stated, the infiltration rate in response to a time invariant pressure head at the ground surface will be highest initially and it will decrease exponentially to a constant value equal to the hydraulic conductivity of the medium at the water content that is associated with the maintained surface water pressure. Due to this change in infiltration rate with time, the wetting front will initially advance relatively rapidly, slowing to a constant rate at late time. Finally, note that the specific results depend on the soil hydraulic properties, which control $K(\theta_{wf})$, and the initial water pressure head, φ_i , which contributes to the value of $\Delta\theta$ over the wetting front. This analysis is commonly used to predict the infiltration rate with time beneath ponded water (positive values of ψ_s). But, some soil science instruments, such as a disk permeameter, have been developed that impose a constant negative water pressure; these also rely on this analysis.

Historically, [Green and Ampt \(1911\)](#) were the first to propose a model to describe infiltration rate as a function of the soil physical parameters. They assumed that a sharp wetting front exists, which separates two regions of constant water content above and below the front, that there is a constant, intermediate pressure head at the wetting front, and that the medium is homogeneous. This leads to following to description of the distance to the wetting front, (L_f [L]), with time as a function of K_s and the change in pressure head, $\Delta\varphi$, and the change in water content, $\Delta\theta$, across the wetting front:

$$L_f = \sqrt{\frac{2K_s t \Delta\varphi}{\Delta\theta}} \quad (6)$$

Example advances of a wetting front during horizontal infiltration following this model are shown in [Fig. 2](#) for a base case of: $K_s = 0.0001 \text{ cm min}^{-1}$; $\Delta\varphi = 30 \text{ cm}$, and $\Delta\theta = 0.15 \text{ cm}^3 \text{ cm}^{-3}$. While changes in any of the three parameters alter the calculated horizontal distance to the sharp wetting front with time, all conditions show similar patterns. The wetting front advances most quickly at early time, slowing as the wetting front moves farther from the source.

A similar expression can be developed for vertical infiltration, considering the influence of gravity. But, it requires root finding or implementation in a numerical model to apply it:

$$L_f - \Delta\varphi \ln\left(1 + \frac{L_f}{\Delta\varphi}\right) = \frac{K_s t}{\Delta\theta} \quad (7)$$

For some agricultural and engineering problems, including surface irrigation, it can be useful to predict the cumulative infiltration that will occur due to the supply of water at a constant pressure for a given time. Widely used relations have been proposed by [Philip \(1957, 1969\)](#), [Knight \(1973\)](#), [Warrick \(1975\)](#), [Brutsaert \(1977\)](#), and [Parlange et al. \(1985\)](#), and others. The simplest, foundational example, developed by [Philip \(1957\)](#) states:

$$i = St^{-0.5} + \gamma K_s \quad (8)$$

Fig. 2 Horizontal advance of a wetting front as a function of changes in the three variables included in the [Green and Ampt \(1911\)](#) equation. Blue dash is the base value. Orange dash is for large K_s . Gray dash is for large $\Delta\varphi$. Green line is for a large change in $\Delta\theta$.

Showing that there is a contribution that is driven by the sorptivity, $S [LT^{-0.5}]$ of the soil, which dominates at early time, and a steady contribution from gravity-driven infiltration that becomes dominant at late time. Note here the factor, γ , which reduces the steady-state infiltration rate due to the impacts of entrapped air, as presented previously.

Example infiltration rates through time for vertical infiltration are shown in Fig. 3 for a base case of: $K_s = 0.0001 \text{ cm min}^{-1}$; $S = 0.1 \text{ cm s}^{-0.5}$, and $\gamma = 0.8 \text{ cm}^3 \text{ cm}^{-3}$. Changes in any of the three parameters alter the time series of infiltration. But, the nature of the curves is highly similar, with large initial infiltration reducing relatively quickly to a near constant rate.

Other parametric expressions have been proposed that capitalize on the predictable transition of infiltration rate from high to steady values. Lewis (1937) proposed a power law decrease in infiltration rate with time:

$$i(t) = akt^{a-1} + i_0 \quad (9)$$

where a is a unitless empirical parameter and $k [LT^{-1}]$ is also treated as empirical with units that strictly vary with the value of a . The addition of the second term, often referred to as the modified Lewis-Kostiakov formula, accounts for a non-zero infiltration rate at late time.

Example infiltration rates through time for vertical infiltration are shown in Fig. 4 for a base case of: $i_0 = 0.0001 \text{ cm min}^{-1}$; $k = 0.1$, and $a = 0.5$. As for the Phillip equation, changing any single parameter changes the specific shape of the curve, but all of the time series show high initial infiltration reducing relatively quickly to a near constant rate.

A similar equation, based on exponentially decaying infiltration rate, was proposed by Horton (1933):

$$i(t) = (i_i - i_0)e^{-kt} + i_0 \quad (10)$$

where i_i is the initial infiltration rate and k is a soil-specific decay rate $[T^{-1}]$ (Fig. 5).

Like the preceding equations, it shows rapid initial infiltration with a steady decay through time. Historically, Horton was among the first to link the behavior of infiltration at the soil profile scale, with watershed scale overland flows (see review by Beven, 2021).

In many cases, infiltration delays the onset of overland flow (consider surface irrigation where applied water must travel over the surface to the end of the field). For these applications, it can be of particular interest to determine how long a given soil, at a given

Fig. 3 Vertical advance of a wetting front as a function of changes in the three variables included in the Philip (1957) equation. Blue line is the base value. Black dash line is for large K_s . Green dash line is for large S . Orange dash line is large γ .

Fig. 4 Vertical advance of a wetting front as a function of changes in the three variables included in the Lewis-Kostiakov (Lewis, 1937) equation. Blue line is the base value. Orange dash line is large i_0 . Gray dash line is large k . Green dash line is large a .

Fig. 5 Vertical advance of a wetting front as a function of changes in the three variables included in the Horton (1941) equation. Blue dash line is the base value. Orange line is large i_0 . Gray dash line is large k . Green dash line is large a .

initial water content, can accept water supplied at a given rate without producing overland flow. As explained above, ponding will only occur if water is applied at a constant rate that exceeds K_s . However, the preceding discussion of infiltration in response to water held at a constant water pressure at the ground surface indicates that a soil should be able to maintain an infiltration rate higher than K_s for some time; the time to ponding would depend on the soil hydraulic properties, the initial conditions, and the application rate. Based on the Philip (1969) expression for infiltration, the time to ponding, t_p [T], can be written as:

$$t_p = \frac{K_s \left(-\varphi_{wf} \right) \Delta\theta}{r(r - K_s)} \quad (11)$$

where r is the applied water rate [LT^{-1}]. Note that the saturated hydraulic conductivity is used because ponding will only occur if $r > K_s$, leading to fully saturated conditions. Some formulations, which depend on soil suction as -1 multiplied by the soil pressure head, do not include the negative sign on the wetting front pressure head. Furthermore, note that – all else being held constant – the time to ponding increases with increased K_s and change in water content across the wetting front and with decreased initial water pressure and water application rate. This analysis has been extended by Assouline et al. (2007) to predict the time of ponding for variable rate application (such as during a natural rainstorm). Considering the discussion of the time to ponding, irrigation could be supplied at a rate that exceeds K_s for some time without causing overland flow; the maximum time would depend on the soil hydraulic properties, initial water pressure in the soil, and the applied rate.

While the early equations describing infiltration focused on one-dimensional horizontal or vertical representations, many real conditions lead to infiltration that is two-dimensional (e.g., beneath an irrigation trench) or three dimensional (e.g., beneath a drip emitter). If water is supplied at a constant rate, such as by an emitter, then horizontal and vertical flow can be thought of as ‘competing’. Water is drawn horizontally by differences in pressure across the wetting front. Vertical water flow is driven by both pressure gradients and gravity. As a result, there should always be more vertical flow than horizontal. But, the degree of difference depends on the relative contributions of pressure and gravity to driving flow. Closed form equations describing multi-dimensional flow are complicated and it is currently more common to solve these problems using numerical models. As a general guideline, conditions that are driven predominantly by gravity (e.g., small pressure differences across the wetting front, relatively wet conditions, and relatively coarse-grained soils) tend to form vertically elongated wetted areas beneath the source. In contrast, conditions that lead to larger contributions from pressure differences (e.g., large pressure differences across the wetting front, relatively dry conditions, and fine-grained soils) result in more spherical wetted areas during infiltration. Regardless of the shape of the wetted area, a wetting front that experiences two- or three-dimensional flow will not progress as far in a given time as would be calculated using a vertical infiltration equation.

If water is supplied at a constant pressure head, then horizontal and vertical infiltration can be thought to combine. Conceptually, as vertical infiltration proceeds, horizontal infiltration draws some water away. This retards the vertical advance of the wetting front, maintaining higher infiltration rates for a longer time. The net result is that two- and three-dimensional infiltration beneath a constant pressure boundary, such as an irrigation furrow, will be greater than that calculated based on a one-dimensional vertical infiltration equation.

Infiltration is a process that occurs at relatively small scales. It can be described by water content and pressure differences that occur on the scale of meters. However, infiltration has impacts across scales. It is often useful to consider infiltration in the context of other hydrologic processes. For example, evapotranspiration describes the removal of water from the soil by plant roots and evaporation. Considering what drives infiltration, you could surmise that the rate of evapotranspiration (the combined result of the plant cover and the evapotranspiration rate of the plants present) would impact the rate of infiltration (Fig. 6). Furthermore, given that precipitation is partitioned into infiltration and runoff, plant cover should affect runoff. Comparing bare ground and a vegetated surface, it is reasonable to expect that the plant cover would reduce the water content in the subsurface, thereby

Fig. 6 Impact of vegetation on the ratio of infiltration to runoff as shown by Bonetti et al. (2021).

maintaining higher infiltration rates for longer. But, Bonetti et al. (2021) showed a more pronounced effect; increased vegetative cover led to changes in the soil structure, due to root growth and decay and associated biological activity, which led to a larger fraction of precipitation infiltrating, leading to a reduced rate of runoff. Similar lines of reasoning will help to predict how other conditions, from soil heterogeneity, to the presence of surface mulch, to surface compaction, to a sloping ground surface may impact infiltration rates. But, in many of these cases, quantitative predictions require the use of unsaturated flow models.

Abstract

Solute transport, defined here as the movement of chemicals in soils and groundwater aquifers, plays a central role in biogeochemical cycling and many other processes. Solute transport can be dominated by advection, diffusion, or dispersion, or by any combination of these. The interaction of a chemical with soil or aquifer solids can slow transport by retardation. The Advection-Dispersion Equation and its two-region or two-site variants have traditionally been applied to solute transport. More modern approaches generalize the Advection-Dispersion Equation. Despite decades of intensive research, our a priori capability to predict solute transport in complex porous media such as soils remains limited.

Key points

- Solute transport plays a major role in soil processes.
- Advection, diffusion, and dispersion are the three modes of solute transport.
- Depending on flow conditions, dispersion can be dominated by diffusion or variations in solute velocity over a broad range of scales.
- Interaction of solutes with soil surfaces by physical or chemical adsorption can slow transport in a process referred to as retardation.
- In many soil applications, a one-dimensional treatment of solute transport may be adequate.
- The Advection-Dispersion Equation (sometimes including enhancements for two-region or two-site conceptualizations) has traditionally been applied to solve solute transport problems.
- Observed dispersivity based on fitting to the Advection-Dispersion Equation is known to increase with the scale of the transport process.
- More recent solute transport models anticipate different types of scaling depending on the structure of a medium's heterogeneity.

Introduction

The movement of chemicals in soils and groundwater aquifers (solute transport) plays a central role in global biogeochemical cycling including carbon emission and sequestration. Human activities have placed many new chemicals into the environment and population pressure continues to increase the loading of wastes and other chemicals to the subsurface. Salinization and other types

of soil degradation can impact food security. Applications of an understanding of solute transport in porous media include the efficacy and fate of agricultural chemicals (fertilizers and pesticides), impacts of irrigation, the treatment and disposal of wastewaters and wastewater treatment products from human, animal, and industrial sources, and contamination resulting from landfills, mining operations, industrial activities, and high-level radioactive waste disposal. Given its relevance and importance for the maintenance of safe water supplies, biogeochemical cycling, nourishment of plants, regulation of the fate of soil-applied chemicals, soil development, and many other critical hydrologic processes, solute transport has long been the focus of intense research in soil science, groundwater hydrology, and chemical engineering. Nevertheless, our a priori capability to predict solute transport remains limited.

Pores may contain water, soil gases, and introduced materials, such as non-aqueous-phase liquids. Chemicals can be transported in any or all of these three fluid phases. The general aspects of transport are similar in each possible phase, so the emphasis here and in much of the solute transport literature is on the transport of chemicals in aqueous solution. A solute is a chemical that is dissolved in a solvent to form a solution.

Three mechanisms operate to transport solutes in soils and aquifers. 'Advection' (or synonymously 'convection' in the solute transport literature) refers to the movement of chemicals with soil fluids and groundwater. Advection often dominates the solute transport process. Diffusion is the omnidirectional spreading of a chemical that results from thermal (Brownian) motion of the fluid and solute molecules. Dispersion results primarily from variations in fluid velocity that occur at all scales. Dispersion is anisotropic and enhanced in the overall direction of flow.

Breakthrough curves display the variation in solute concentration as a function of time or distance. These measurements and the advection-dispersion equation are the primary tools used in the evaluation of solute transport.

Solutes can interact strongly with soil surfaces by physical or chemical adsorption and their transport can be appreciably slowed in a process known as retardation. Repulsion or exclusion of solutes from soil surfaces can result in transport more rapid than that of the carrier fluid.

Transport processes

Advection

In the most simplistic sense, dissolved solutes are carried along with moving soil fluids. Here, 'fluid' refers to either a gas or a liquid phase; simultaneous treatment of interacting gas and liquid phases requires coupling of the treatment described below. A fluid flowing through a porous medium at a flux q (volume of fluid per unit area of soil per unit time) with a solute concentration C (mass of solute per unit volume of fluid) carries with it a solute flux $J_c = qC$ (mass of solute per unit area of soil per unit time). The mean velocity of the flow v (and the solute, assuming no losses, production, or interaction with the solid phase) can be computed from knowledge of the flux q and the volumetric fluid content θ via $v = q/\theta$. Under steady flow, $x = vt$ (where v is the magnitude of v), and the distance x traveled by an average solute molecule in time t , or the time t needed for the solute to traverse a given distance x , can be calculated. The advective solute flux J_c can also be written in terms of the mean velocity, the concentration, and the fluid content: $J_c = v\theta C$. In some instances, for example when the solute source is continuous and the solute concentration is uniform in the flowing fluid, advection dominates the solute transport process and may be the only process that need be considered.

Diffusion

Diffusion is the spreading of a solute due to thermally induced Brownian motion. It is generally considered to be omnidirectional and driven by concentration gradients according to concentration-independent coefficients, though close study reveals that it is more complicated when solute concentrations are large. Under the typical assumptions, diffusion can be treated with Fick's first law, which gives the diffusive solute flux J_s as a function of the concentration gradient ∇C and the bulk diffusion coefficient D_b , i.e., $J_s = -D_b \nabla C$.

In soils, the diffusion paths are obstructed by solid particles and solutes are constrained to follow the tortuous, connected pore network. The connected network changes as the fluid content changes. The effective diffusion coefficient D_e must therefore be computed from the bulk diffusion coefficient and the soil water content and porosity. A commonly used empirical expression for the estimation of the effective diffusion coefficient is $D_e = D_b \theta^{10/3} / \phi^2$, where ϕ is the porosity.

Dispersion

Consideration of saturated water flow in perhaps the simplest possible pore geometry—a straight capillary tube with circular cross section—provides insight into the processes that take place in the more tortuous and convoluted pore networks that characterize natural porous media. The velocity of fluid in such a tube depends on the pressure drop between the ends of the tube (a distance L apart), the tube's radius r , and the dynamic viscosity η . In general, the velocity is not uniform across the tube's cross section. In the laminar flow regime, generally thought to apply to water movement in most soils, the velocity profile in a capillary tube is parabolic:

$$v(y) = 2v \left(1 - \frac{y^2}{r^2} \right) \quad (1)$$

where $v(y)$ is the velocity as a function of radial distance y from the tube center.

Fig. 1 Schematic velocity profile or solute front position in an idealized cylindrical capillary tube. Flow from left to right.

The mean velocity v can readily be determined from Stokes law in the form:

$$v = \frac{r^2 \Delta P}{8\eta L} \quad (2)$$

According to this model, the maximum velocity at the center of the tube ($y = 0$) is $2v$, and there is zero velocity at the tube's inner surface ($y = r$).

A solute introduced at concentration C_0 at the upstream end of the tube at time zero ($t = 0$) will be convected rapidly in the center of the tube and more slowly near the tube's surface (Fig. 1). Taking integrated samples from various cross sections along the tube at a later time ($t > 0$) and assuming no diffusion results in the collection of fluid containing no solute and fluid containing solute at the introduced concentration C_0 in various proportions. Dilution of the solute with solute-free fluid in the sample occurs according to the relative cross-sectional areas of the solute paraboloid and the solute-free fluid. The relative concentration as a function of time t or distance along the pipe x can be computed from $\frac{C}{C_0} = 1 - \frac{4\eta x}{Gr^2 t}$ (for $t > \frac{4\eta x}{Gr^2}$ and $x < \frac{Gr^2 t}{4\eta}$), where G is the pressure gradient over a length of the pipe ($\Delta P/L$) or a body force like the product of gravity and density (ρg) for a vertical tube. Thus, the solute front is spread out or dispersed due to velocity variations in the pipe.

In addition to the dispersion introduced by velocity variations within individual pores, the variable sizes and path lengths of pores in a natural porous medium and mixing at pore intersections also contribute to dispersion. Buoyancy factors may cause fingering and attendant mixing of a dense solution into a less-dense one. If the dispersion arises from such velocity and path-length variations, and hydrodynamic mixing alone, it is referred to as 'hydrodynamic dispersion.' The impact of variable velocities, path lengths, and mixing accumulates through the entire hierarchy of scales pertinent to the particular porous medium under consideration. Unsaturated conditions found in most soils generally add additional complexity to flow fields within individual pores and increase the tortuosity. Hence, the degree of dispersion is usually greater under partially saturated conditions than in the fully saturated case.

Diffusion results in a spreading of solute fronts similar to that induced by dispersion. It is generally not possible to separate out the effects of diffusion and dispersion. They are typically considered to be additive with a lumped diffusion–dispersion coefficient D_d given by $D_d = D_h + D_e$, where D_h is the coefficient of hydrodynamic dispersion. The diffusive–dispersive solute flux J_d is then treated assuming a Fick's law-like formulation: $J_d = -D_d \nabla C$.

The diffusion-dispersion coefficient has been notoriously difficult to estimate a priori and is generally determined via inverse modeling. Excellent computer programs for its determination from transport measurements are available (Parker and van Genuchten, 1984; Toride et al., 1995). However, this reliance on measurements of the actual transport process for parameter estimation is unfortunate, because the measurements are difficult and time-consuming, and can rarely be carried out at the scale of interest.

Inside a pore, the dimensionless Peclet number ($Pe \equiv vl/D_b$, with l a characteristic length) indicates the relative importance of diffusion and advection; large values of Pe indicate an advection-dominated process, while small values of Pe indicate the dominance of diffusion. Similarly, the dimensionless diffusion-dispersion coefficient $D^* \equiv D_d/D_b$ reflects the relative importance of hydrodynamic dispersion and diffusion. For porous media with well-defined characteristic lengths (i.e., bead diameter in packed beds of uniformly sized glass beads), D^* can be estimated from Pe . Different classes of behavior have been proposed based on the observed relationship between Pe and D^* (Fig. 2). Class I is characterized by very slow flow and the dominance of diffusion. Class II is transitional, with approximately equal and additive hydrodynamic dispersion and diffusion. Hydrodynamic dispersion dominates the dispersion process in classes III and above. In class III, the role of diffusion is still nonnegligible, but it ceases to be significant in class IV. Finally, in class V, the velocity is so high that the flow of many fluids is turbulent.

Dimensionality

The dimensionality of the solute transport process is an important factor. In many soil science applications, for example the uniform application of a pesticide to the soil surface, the process can frequently be treated as one-dimensional. However, in other instances

Fig. 2 Empirical relationship between dimensionless dispersion coefficient (D^*) and Peclet number (Pe) with data for uniformly sized particle beds. two- or three-dimensional aspects of the transport process cannot be neglected. The problem can be viewed in terms of the geometrical configurations of the source and sink of interest. In the case of uniform soil application, the source is considered planar and the sink may be a planar water table. In contrast, a chemical spill limited to a small area overlying a thick vadose zone may need to be considered a point source in a fully three-dimensional system where solute may be dispersed both horizontally and vertically.

Even in a flow field that is macroscopically one-dimensional, dispersion is an anisotropic process and is enhanced in the direction of flow relative to transverse directions. A fully three-dimensional treatment of dispersion therefore requires a tensorial representation. For simplicity, we will restrict our discussion of solute transport to one-dimensional flow, where the effects of dispersion are embodied in a single scalar, the longitudinal dispersion coefficient, and the related longitudinal dispersivity.

Longitudinal dispersivity

The relationship between the one-dimensional diffusion-dispersion coefficient and mean pore-water velocity is frequently modeled with the empirical equation $D_d = m + \alpha v^n$, where m and n are fitting parameters, and α is the longitudinal dispersivity. In the hydrodynamic dispersion-dominated regime, the magnitude of m is negligible and n approaches unity. Under these conditions, the longitudinal dispersivity has dimensions of length and can be defined as $\alpha \equiv D_d/v$.

The dispersivity ideally would be a constant for a particular porous medium, and efforts have been made to relate it to other medium properties. In general, it has been observed that under saturated conditions the magnitude of the dispersivity depends upon the scale of the domain under consideration (Fig. 3). The reasons for this scale dependency are unclear, but, at a macroscopic scale, the phenomenon may be related in part to spatial variations in the underlying saturated hydraulic conductivity field. New approaches for treating the relationship between α and scale have recently appeared and are described further below.

Another important influence on dispersivity under saturated conditions is soil structure, as influenced by differences in texture. In general, sandy soils have a narrower range of pore sizes and a smaller dispersivity than finer-grained soils. The combined effects of measurement scale and soil texture on α for soil columns (based on empirical relationships between dispersivity and soil hydraulic parameters and power law scaling of dispersivity with length) are shown in Fig. 4.

Breakthrough curves

Plotting the downstream changes in solute concentration against time at a fixed position or against distance from the source at a fixed time results in a breakthrough curve. Breakthrough curves generated from a continuous source will be approximately sigmoidal (resembling a cumulative Gaussian distribution function) provided the column Peclet number ($Pe_c \equiv v L/D_d$, where L is the column length) is large enough. Complete breakthrough occurs when the effluent concentration (C) is equal to the influent concentration (C_0), giving a relative concentration $C/C_0 = 1$. If the solute is introduced as a short pulse, complete breakthrough may not be attained and the solute concentrations will eventually fall and return to background levels. In this case, a breakthrough curve will resemble a Gaussian density function for adequately large column Peclet numbers. Small column Peclet numbers (usually due to short columns or high dispersion coefficients) result in asymmetrical breakthrough curves. The full behavior of the breakthrough curve is described by an inverse Gaussian distribution.

It is common to plot breakthrough curves from soil columns as relative concentration against the number of pore volumes eluted from the column. Because the computation of eluted pore volume incorporates time and column length, it is a means of making the x -axis non-dimensional. The pore volume in a column of length L and cross-sectional area A is $LA\theta$. The volume of fluid eluted over time t is $Atv\theta$. Thus, the number of pore volumes T eluted at any given time t is $(Atv\theta)/(LA\theta)$ or $T = tv/L$.

Fig. 3 Apparent dispersivity versus scale for laboratory and field measurements. Adapted from Neuman SP (1995) On advective transport in fractal permeability and velocity fields. *Water Resources Research* 31: 1455–1460, American Geophysical Union, with permission.

Fig. 4 Approximate effects of measurement scale and soil texture on dispersivity for soil columns based on empirical relationships between dispersivity and soil hydraulic parameters and power-law scaling of dispersivity with length.

This representation has instructive and conceptual benefits because, during piston-type flow where the solute front is not dispersed, it is fairly obvious that, after the input of one pore volume of solution containing solute at concentration C_0 into an initially solute-free column, the concentration of the effluent will immediately jump from $C = 0$ to $C = C_0$. This is shown in Fig. 5 where it corresponds to the curve with infinite column Peclet number. Decreasing the column Peclet number (e.g., by increasing the dispersion coefficient or shortening the column) causes spreading of the solute elution. Some solute travels faster than the mean velocity and elutes before one pore volume of fluid has entered the soil, while some travels slower than the mean and elutes after one pore volume of fluid is injected. When the column Peclet number is relatively high (Fig. 5; $Pe_c = 1000$ and $Pe_c = 100$), the early- and late-arriving solute masses are approximately equal, and the breakthrough curve is approximately sigmoidal and well described by a cumulative Gaussian distribution. The value of C/C_0 at one pore volume on this curve is approximately 0.5; this is considered a

Fig. 5 Effect of column Peclet number (Pe_c) on relative concentration (C/C_0) in column effluent for a step-change application of solute.

Fig. 6 Effect of column Peclet number on concentration in column effluent for a pulse application of solute. Pulse duration is 0.2 pore volumes.

hallmark of an ‘ideal’ solute transport process by many practitioners, with deviations calling for elaborate modifications to standard theory. Inspection of the gross asymmetry introduced by decreases in the column Peclet number (Fig. 5; $Pe_c = 10$ and $Pe_c = 1$) indicates that such deviations should be expected under many conditions. This effect is pronounced for solute pulses, and is perhaps somewhat counterintuitive in that smaller column Peclet numbers (more dispersion) can actually lead to higher peak concentrations than larger ones (Fig. 6; $Pe_c = 1$ vs. $Pe_c = 10$).

Adsorption and exclusion

Adsorption of solutes on to soil solids generally causes them to move at a fraction of the velocity of the fluid. The most simplistic (and common) treatment of adsorption involves the assumption of a linear adsorption isotherm that relates the adsorbed concentration on soil solids (C_s , mass of solute per unit mass of soil) to the concentration in solution at equilibrium via $C_s = K_d C$, where K_d is the soil/water partitioning or distribution coefficient with dimensions $L^3 M^{-1}$. The linear isotherm is primarily applicable to low solute concentrations and adsorption of a nonspecific physical nature.

K_d can be measured independently in the laboratory by mixing soil and solution and determining the equilibrium partitioning of the solute between the solid and fluid. In practice, however, the K_d of organic solutes is often estimated from the organic carbon partitioning coefficient $K_{oc}(L^3 M^{-1})$ using $K_d = K_{oc} f_{oc}$, where $f_{oc}(MM^{-1})$ is the mass fraction of organic carbon in a soil. There are many tables of K_{oc} values available (e.g., Table 1) and f_{oc} is a commonly measured soil property. Solutes with low K_d values have a low affinity for soil surfaces and, for a conservative solute, $K_d = 0$. Other solutes can be strongly bound to soil and have very high K_{oc} and K_d values.

Exclusion, in which a solute is repelled from solid surfaces and hence concentrated in more rapidly flowing fluid away from pore walls, has also been observed. In particular, negatively charged anions are often excluded from negatively charged soil mineral surfaces. Thus, they may elute earlier from a column than the carrier fluid with which they were introduced.

Adsorption and exclusion phenomena are often incorporated into solute transport models through the use of a retardation factor, R , given by:

$$R = 1 + \frac{\rho_b K_d}{\theta} \quad (3)$$

where ρ_b is the soil bulk density. For conservative solutes, $R = 1$, for sorbing solutes, $R > 1$, and, for excluded solutes, $R < 1$.

Fig. 7 Effects of retardation (R) and exclusion on breakthrough curve at $Pe_c = 10$.

Fig. 7 shows the effects of solute adsorption and exclusion relative to the breakthrough curve for a conservative solute ($R = 1$, $Pe_c = 10$, in Fig. 7). The retarded curve ($R = 2$, $Pe_c = 10$, in Fig. 7) shows a considerable delay in solute elution. Note also that the degree of solute dispersion is enhanced, even though the dispersion coefficient itself is unchanged. Conversely, the curve representing anion exclusion ($R = 0.7$, $Pe_c = 10$, in Fig. 7) shows early elution of the solute and less dispersion of the solute front.

For a continuous source under piston flow conditions, the solute front advances without dispersion and the velocity of the front (v_s) relative to the mean velocity of the fluid is $v_s = v/R$. With moderate dispersion and adequate transport length, the front assumes a sigmoidal shape, and v_s represents the position of the front defined by $C/C_0 = 0.5$. For a pulse source, v_s characterizes the velocity of the solute center of mass. In some instances, these simple relations may be adequate for estimating the solute front position or peak arrival. However, dispersion can play a critical role in determining the peak concentration and its duration. Evidence suggests that brief exposures to high concentrations may be exceptionally detrimental to human health in some instances.

Advection-dispersion equation and other solute transport models

The advection-dispersion equation (ADE, or convection-dispersion equation, CDE) has long been used as a model for solute transport. It can be derived from the flux terms described above (here taken as one-dimensional in the x direction) and a solute mass balance. The flux of solute due to convection is $J_c = v\theta C$, while the diffusive-dispersive flux is $J_d = -D_d \partial C / \partial x$. Combining these two fluxes, we have $J = J_c + J_d = v\theta C - D_d \partial C / \partial x$. Consider a volume of soil (Fig. 8) and steady one-dimensional flow. If the inflow of solute mass at $x = 0$ and the outflow at $x = L$ are not equal, then mass must accumulate in or be lost from the soil volume. Assuming for the moment that the solute can only be stored in the fluid, then either the volume of fluid at a constant concentration—given by $AL\theta$ —must change, or the solute concentration (C) in a fixed volume of fluid must change. The dimensions of the volume AL are constant and, when the flow is steady, the fluid content θ is constant. Therefore, only the concentration can change. The time rate of change in solute mass inside the volume is $AL\theta dC/dt$.

The difference in the inflow and outflow of mass per unit time can be written as $(\text{mass}_{\text{out}} - \text{mass}_{\text{in}})/\Delta t$. The flux J is the mass per unit area and time, so an equivalent expression is $A(J_{x=L} - J_{x=0})$. The spatial rate of change in solute flux is $\partial J / \partial x$, and the difference between the outflow and inflow is $A[J_{x=0} - (J_{x=0} + L \partial J / \partial x)]$. Equating this difference to the change in the stored mass gives:

$$AL\theta \frac{dC}{dt} = A \left[J_{x=0} - \left(J_{x=0} + L \frac{\partial J}{\partial x} \right) \right] \quad (4)$$

Fig. 8 Elemental volume, with one-dimensional solute fluxes. J , flux; C , concentration; L , length; θ , volumetric fluid content.

which readily simplifies to:

$$\theta \frac{\partial C}{\partial t} = - \frac{\partial J}{\partial x} \quad (5)$$

Incorporating our earlier expression for the solute flux J , we have:

$$\theta \frac{\partial C}{\partial t} = - \frac{\partial (v\theta C - D_d \frac{\partial C}{\partial x})}{\partial x} \quad (6)$$

Finally, with D_d , v , and θ constant, the ADE is:

$$\frac{\partial C}{\partial t} = -v \frac{\partial C}{\partial x} + \frac{D_d}{\theta} \frac{\partial^2 C}{\partial x^2} \quad (7)$$

Eq. (7) is often written with D_d/θ replaced by an apparent diffusion-dispersion coefficient D .

The ADE can readily be modified to incorporate adsorption by accommodating solute storage on the soil solids in addition to storage in the fluid phase. Thus, the storage term becomes $AL\theta C + AL\rho_b C_s$ or, in terms of the solute concentration in the fluid and assuming a linear isotherm, $AL(\theta C + \rho_b K_d C)$. Then Eq. (6) becomes:

$$(\theta + \rho_b K_d) \frac{\partial C}{\partial t} = - \frac{\partial (v\theta C - D_d \frac{\partial C}{\partial x})}{\partial x} \quad (8)$$

Note that this formulation also assumes that the adsorption equilibrium is attained instantaneously. Alternative derivations that remove this restriction are available. Removing the assumed constant variables (v , q and D_d) from the space derivative and dividing by θ yields:

$$R \frac{\partial C}{\partial t} = -v \frac{\partial C}{\partial x} + \frac{D_d}{\theta} \frac{\partial^2 C}{\partial x^2} \quad (9)$$

where R is the retardation factor given by Eq. (3).

Other isotherms, including the Langmuir (which introduces an adsorption maximum) and the Freundlich (which introduces a nonlinear concentration dependence), have been used to describe adsorption during solute transport. Realistic transport simulations of reactive species must often rely on considerably more complex, coupled reaction-transport models.

Many chemical species are susceptible to production or decay in the soil. Zero-order decay proceeds at a rate that is independent of the concentration of the substance where $\partial C/\partial t = kC$, where k is the rate constant (T^{-1}). Such potential sinks and sources, as well as physical sinks (e.g., root uptake) can readily be incorporated into the ADE.

Estimates of the parameters in the ADE can be obtained by moment analysis of solute breakthrough curves. A number of analytical solutions for the ADE are also available. Depending on the concentration detection mode (column effluent or 'resident' pore water) the following solutions have been recommended for a step change in concentration from C_0 to C at time $t = 0$ (Kreft and Zuber, 1978):

$$\text{Flux mode : } \frac{C}{C_0} = \frac{1}{2} \operatorname{erfc} \left[\frac{Rx - vt}{2(DRt)^{\frac{1}{2}}} \right] + \frac{1}{2} \exp \left(\frac{vx}{D} \right) \operatorname{erfc} \left[\frac{Rx - vt}{2(DRt)^{\frac{1}{2}}} \right] \quad (10)$$

$$\text{Resident mode : } \frac{C}{C_0} = \frac{1}{2} \operatorname{erfc} \left[\frac{Rx - vt}{2(DRt)^{\frac{1}{2}}} \right] + \frac{1}{2} \left(\frac{v^2 t}{\pi D r} \right)^{\frac{1}{2}} \operatorname{erfc} \left(- \frac{(Rx - vt)^2}{4DRt} \right) - \frac{1}{2} \left(1 + \frac{vx}{D} + \frac{v^2 t}{DR} \right) \exp \left(\frac{vx}{D} \right) \operatorname{erfc} \left[\frac{Rx + vt}{2(DRt)^{\frac{1}{2}}} \right] \quad (11)$$

Here 'exp' and 'erfc' are the exponential function and complementary error function, respectively. The differences between the two solutions become appreciable in highly dispersive systems. Fig. 9 shows the solutions at $Pe_c = 1$. More complex and multidimensional formulations of the ADE generally require numerical solutions.

Two-region advection-dispersion equation

This equation, also referred to as the 'mobile-immobile water model' (MIM), is a special case of the ADE, in which the liquid phase is conceptually divided into two distinct (mobile and immobile) regions. Advective-dispersive solute flux occurs within the mobile water region, with solutes entering and leaving the immobile water region by diffusion. The ADE for solute transport within the mobile water region can then be written as:

$$\frac{\partial C_m}{\partial t} = D \frac{\partial^2 C_m}{\partial x^2} - v_m \frac{\partial C_m}{\partial x} - \left(\frac{\theta_{im}}{\theta_m} \right) \frac{\partial C_{im}}{\partial t} \quad (12)$$

where the subscripts 'm' and 'im' refer to the mobile and immobile regions, respectively. The kinetic term $\theta_{im} dC_{im}/dt$ is usually expressed in terms of a first-order rate constant k and the concentration difference $C_m - C_{im}$. Eq. (12) can be solved analytically with or without making any assumptions about the spatial arrangement of solids and voids. In the first case, the mobile and immobile

Fig. 9 Effect of concentration detection mode on breakthrough curve at $Pe_c = 1$.

liquid regions are explicitly defined in terms of pore-space geometry. The majority of these models are for packed beds of uniform-sized, spherical soil aggregates; here θ_m is the macropore or inter-'aggregate' water content, and θ_{im} is the intra-'aggregate' water content. While it is possible to extend this approach to nonuniform and non-spherical aggregates, its predictive capability is limited. This is because the relationship between packed beds of sieved aggregates and the pore characteristics of undisturbed soil is far from clear. In the second case, the mobile-immobile water fraction is simply a fitting parameter.

Eq. (12) is commonly employed to parameterize asymmetric solute breakthrough curves with 'heavy tails.' Deviations from the Gaussian distribution associated with the ADE are often observed in breakthrough curves where more of the observed distribution is in the tails. Improvements in fit associated with the MIM as compared to the ADE can probably often be attributed to the presence of additional model parameters. Since it is rarely possible to measure the mobile and immobile water fractions independently, this parameter is usually estimated inversely. A two-site conceptualization of the soil, where a fraction of the adsorption sites are considered to have non-instantaneous adsorption, leads to an equivalent mathematical formulation.

Multi-rate mass transfer models

The multi-rate mass transfer (MRMT) approach (Haggerty and Gorelick, 1995; Villermanx, 1987) generalizes the MIM presented in the previous Section in that it accounts for different types of linear mass transfer processes that can occur at different rates. This includes diffusion into immobile regions, and kinetic first-order surface reactions. The MRMT model describes advective-dispersive transport in a single mobile continuum, as the MIM, and linear mass transfer between the mobile and an ensemble of immobile continua. The weight of the j th immobile continuum is denoted by p_j . The total immobile concentration c_{im} is obtained by the weighted sum over the local immobile concentrations $c_{im}^{(j)}$,

$$C_{im} = \sum_j p_j \beta_j C_{im}^{(j)} \quad (13)$$

where $\beta_j = R_{im}\theta_{im}/R_m\theta_m$ is the capacity coefficient of the j th immobile zone, with R_m the retardation coefficient of the mobile region, and $R_{im}^{(j)}$ and $\phi_{im}^{(j)}$ the retardation coefficients and saturations of the immobile regions. The immobile concentrations are related to the mobile concentration through the convolution product.

$$C_{im}^{(j)} = \int_0^t dt' \varphi^{(j)}(t-t') C_m(t'). \quad (14)$$

The memory function $\varphi^{(j)}(t)$ encodes the information on the physics of the linear mass transfer process. Combining Eqs. (13) and (14), one can write the total immobile concentration as.

$$C_{im} = \beta \int_0^t dt' \varphi(t-t') C_m(t') \quad (15)$$

where the global memory function is defined by $\varphi(t) = \sum_j p_j \beta_j \varphi^{(j)}(t)$ and the capacity coefficient by $\beta = \sum_j p_j \beta_j$. The governing equation for the mobile solute concentration is then given by

$$\frac{\partial C_m}{\partial t} + \beta \frac{\partial}{\partial t} \int_0^t dt' \varphi(t-t') C_m(t') + v \frac{\partial C_m}{\partial x} - D \frac{\partial^2 C_m}{\partial x^2} = 0. \quad (16)$$

For linear first-order kinetic mass transfer, the memory function is given by $\varphi^{(j)}(t) = k_i \exp(-k_i t)$, where k_i denotes the mass transfer rate. For diffusive mass transfer into layered immobile regions, the memory function can be expressed in Laplace space by (Harvey and Gorelick, 1995)

$$\bar{\varphi}^{(j)}(\lambda) = \frac{1}{\sqrt{\lambda \tau_D^{(j)}}} \tanh\left(\sqrt{\lambda \tau_D^{(j)}}\right), \quad (17)$$

where $\tau_D^{(j)} = l_j^2/D$ is the characteristic diffusion time within the immobile layer of thickness l_j . The Laplace transform is defined in (Abramowitz and Stegun, 1972), Laplace transformed quantities are marked by an overbar, the Laplace variable is denoted by λ . Memory functions for spherical and cylindrical immobile geometries can be found for example in Harvey and Gorelick (1995). Memory functions for diffusion into immobile zones characterized by heterogeneous diffusion properties and irregular geometries are discussed in Gouze et al. (2008). The MRMT model can in principle be derived by volume averaging of a composite heterogeneity model that distinguishes a connected mobile region and unconnected immobile regions. The averaging volume is large enough such that it contains a representative sample of immobile zones that does not vary in space and can be characterized by the probability distribution p_j . In other words, the heterogeneity distribution is assumed to be stationary. This is why at each point in space, the MRMT model quantifies in principle a distribution of concentration values and not only a single value as advection-dispersion models do.

Based on this phenomenology, the MRMT model can in principle be parameterized based on the characterization of the geometry and mass transfer processes of the immobile regions. Examples are layered media such as single fracture- matrix systems (Maloszewski and Zuber, 1985). In this case, the memory function decays as $\varphi(t) \sim t^{-1/2}$, which implies a decay of the breakthrough curve in response to a pulse injection as $t^{-3/2}$, which is characteristic of matrix diffusion. Fig. 10 shows breakthrough data from a tracer experiment in fractured rock that shows these signatures. The MRMT model captures the long time tailing and the delay in the peak behavior (Hadermann and Heer, 1996). Depending on the distributions of characteristic mass transfer time scales, the MRMT approach can model power-law tailing of solute breakthrough curves (Haggerty et al. 2000), and general breakthrough curve tailing.

Continuous time random walk models

The continuous time random walk (CTRW) approach (Berkowitz et al. 2006) accounts for the fact that mass transfer times in heterogeneous media are distributed. It has found broad application for the modeling of non-Fickian transport in porous and fractured media from pore to regional scale. The CTRW approach is based on a similar phenomenology as the MRMT approach. In fact, it has been shown, that the two approaches are, under certain conditions, mathematically equivalent (Dentz and Berkowitz 2003).

The CTRW approach models solute transport through the propagation of solute particles over distributed space and time increments. Note that the spatial particle distribution is a measure for the solute concentration. The distribution of space and time increments reflects the medium and microscale transport properties. To illustrate this approach, we consider media that are

Fig. 10 Experimental breakthrough curve for uranine (circles) fitted by a MRMT model for matrix diffusion (MD, solid line), and ADE estimate (dashed line). Adapted from Fig. 3 in Hadermann J and Heer W (1996) The Grimsel (Switzerland) migration experiment: Integrating field experiments, laboratory investigations and modelling. *Journal of Contaminant Hydrology* 21(1–4): 87–100. doi: 10.1016/0169-7722(95)00035-6.

characterized by a single characteristic heterogeneity length scale l_c , which may be the pore length for pore-scale applications, or the correlation scale of log-hydraulic conductivity for Darcy-scale applications. Mass transfer properties such as velocity or retardation, are assumed to be constant over this length scale. Thus, as a solute particle moves through the medium, its motion can be modeled through spatial transitions over the length l_c associated with a transition time τ . Subsequent transition times are modeled as independent identically distributed random variables. Their distribution $\psi(t)$ can in principle be related to microscopic mass transfer processes such as spatially variable advection or retardation properties. In many applications, the transition time distribution has been modeled by parametric functions such as truncated power-law distributions whose parameters are then fitted, for example to observed breakthrough data (Berkowitz et al. 2006). The phenomenological basis of CTRW reflects that for heterogeneous media, the transport properties are imprinted in the medium structure. Thus, it is able to describe and predict heterogeneity-induced large scale transport phenomena such as breakthrough curve scaling, forward and backward tails in spatial solute distribution as well as non-linear evolution of solute dispersion.

As mentioned above, the CTRW approach propagates solute particles in space and time according to

$$x_{n+1} = x_n + l_c, \quad t_{n+1} = t_n + \tau_n, \quad (18)$$

where x_n and t_n are the particle position and time after n random walk steps. The particle position at a given time t is given by $x(t) = x_{n_t}$, where $n_t = \max(n | t_n \leq t)$ is the number of random walk steps before time t . It can be shown (Berkowitz et al., 2006) that the distribution c of particles that move according to Eq. (18) satisfy the non-local advection dispersion equation

$$\frac{\partial C}{\partial t} + \int_0^t dt' M(t-t') \left[v \frac{\partial C(t')}{\partial x} - D \frac{\partial^2 C(t')}{\partial x^2} \right] = 0. \quad (19)$$

where the velocity is $v = l_c/\tau_c$ and the dispersion coefficient is $D = l_c^2/2\tau_c$. If ψ has a finite mean, the characteristic time scale is equal to the mean transition time $\tau_c = \tau$. The memory function M can be written in Laplace space as

$$\bar{M} = \frac{\tau_c \lambda \bar{\psi}}{1 - \bar{\psi}} \quad (20)$$

For the exponential transition time distribution $\psi = \exp(-t/\tau_c)$, the memory function reduces to $M = \delta(t)$ and the non-local Eq. (19) reduces to the advection-dispersion equation. Solute transport based on the CTRW approach can be modeled numerically using random walk particle tracking methods based on Eq. (18) or using grid-based methods based on the non-local advection-dispersion equation (Eq. 19). Analytical results can be obtained for the long-time scaling of breakthrough curves and spatial moments.

For a transition time distribution that behaves asymptotically as $\psi \sim t^{-1-\gamma}$, the solute breakthrough curves in response to a pulse show the same scaling. The time evolution of the first and second centered moments of the concentration distribution for a pulse-like initial condition depends on γ -range (Shlesinger, 1974). For $0 < \gamma < 1$, the center of mass position scales as t^γ and the second centered moment as $t^{2\gamma}$. For $1 < \gamma < 2$, the scalings are linear for the center of mass and $t^{3-\gamma}$ for the second centered moments. For $\gamma > 2$, both center of mass position and second-centered moment evolve linearly at asymptotic times. Note that the transition time distribution ψ in general does not behave as a power-law. Its shape is determined by the heterogeneity distribution, as for example the distribution of flow speeds or retardation coefficients. If ψ scales as a power-law in a certain time regime, the corresponding behavior of the breakthrough curve and spatial moments can be estimated from the above scaling relations.

Fig. 11 shows complementary cumulative breakthrough data from tracer experiments in Berea sandstone. The CTRW fit reproduces the long tail, which is a manifestation of solution retention mechanisms due to small scale medium heterogeneities (Cortis and Berkowitz, 2004).

Fractional advection-dispersion models

Fractional advection-dispersion models are generalizations of the advection-dispersion equation based on fractional derivatives in space or time. They have been used for the modeling of non-Fickian transport features in porous and fractured media (Benson et al. 2013). Time-fractional approaches are linked to the MRMT and CTRW approaches for memory functions and transition time distributions that decay as pure power-laws. Space-fractional advection-dispersion models describe random walks that are characterized by broad distributions of transition lengths. A comprehensive treatise on time and space fractional transport models and their relation to stochastic processes can be found in the textbook by Meerschaert and Sikorskii (2011). In the following, we briefly summarize time- and space-fractional advection-dispersion models.

Time-fractional advection-dispersion equations

The time-fractional advection-dispersion equation (t-FADE) is linked to a CTRW that describes particle motion through the equations

$$x_{n+1} = x_n + v\Delta s + \sqrt{2D\Delta s}\xi_n, \quad t_{n+1} = t_n + \Delta s^{1/\gamma}\eta_n \quad (21)$$

Fig. 11 CTRW versus ADE fits of experimental BTC data of a Berea sandstone core. Symbols denote experimental data from Scheidegger (1959), the solid line the CTRW fit, and the dashed line the ADE fit. Adapted from Fig. 2 in Cortis A and Berkowitz B (2004) Anomalous transport in “classical” soil and sand columns. *Soil Science Society of America Journal* 68(5): 1539–1548. doi: 10.2136/sssaj2004.1539.

where v and D are a velocity and a dispersion coefficient, Δs is termed an operational time increment and η_n is an identical independently distributed random variable whose distribution $\psi_\eta(t)$ is Lévy alpha-stable. Its Laplace transform is given by $\psi_\eta(\lambda) = \exp(-\alpha\lambda^\gamma)$ with $0 < \gamma < 1$. α is a scale parameter of units T^γ . It decays as the power law $t^{-1-\gamma}$. It can be shown that the concentration c satisfies the fractional advection-dispersion equation (Meerschaert and Sikorskii 2011).

$$\alpha \frac{\partial^\gamma C}{\partial t^\gamma} + v \frac{\partial C}{\partial x} - D \frac{\partial^2 C}{\partial x^2} = \alpha \frac{t^{-\gamma} C(0)}{\Gamma(1-\gamma)} \quad (22)$$

in the limit $\Delta s \rightarrow 0$. The Riemann-Liouville fractional derivative on the left side is a non-local operator that is defined by

$$\frac{\partial^\gamma C}{\partial t^\gamma} = \frac{\partial}{\partial t} \int_0^t dt' \frac{(t-t')^{-\gamma}}{\Gamma(1-\gamma)} C(t'). \quad (23)$$

The t-FADE describes power-law decay of breakthrough curves at $t^{-1-\gamma}$. Generalizations of this approach for exponents $1 < \gamma < 2$ can be found in Meerschaert et al. (2010).

Time-fractional mobile-immobile models (Benson et al. 2013) are related to the MRMT approach discussed above. For the memory function $\varphi(t) = \alpha t^{-\gamma}/\Gamma(1-\gamma)$, the governing equation (Eq. 4) is then by definition of the Riemann-Liouville fractional derivative given by

$$\frac{\partial C_m}{\partial t} + \beta \alpha \frac{\partial^\gamma C_m}{\partial t^\gamma} + v \frac{\partial C_m}{\partial x} - D \frac{\partial^2 C_m}{\partial x^2} = 0. \quad (24)$$

For $\gamma = 1/2$, this equation describes transport under fracture-matrix interaction with a semi-infinite matrix.

Space-fractional advection-dispersion equation

The phenomenology of space-fractional advection dispersion models is different from the time-fractional models discussed above, which account for the existence of broad distributions of mass transfer times in heterogeneous media as expressed by power-law distributions of transition times $\psi(t)$, and power-law tails of the memory function $\phi(t)$.

Space-fractional approaches, in contrast, model solute transport through long range spatial interaction. The space-fractional advection-dispersion model can be written as (Benson et al. 2000)

$$\frac{\partial C}{\partial t} + v \frac{\partial C}{\partial x} - D \frac{1+p}{2} \frac{\partial^\gamma C}{\partial x^\gamma} - D \frac{1-p}{2} \frac{\partial^\gamma C}{\partial (-x)^\gamma} = 0, \quad (25)$$

where $0 \leq p \leq 1$ describes the skewness of c , D is a generalized diffusion coefficient of unit L^γ , and the order of the fractional derivative is $0 < \gamma < 2$. This equation is equivalent to the following Langevin equation for the motion of solute particles (Meerschaert and Sikorskii 2011)

$$x_{n+1} = x_n + v\Delta t + \Delta t^{1/\gamma} \xi_n(\gamma, p), \quad (26)$$

where $\xi_n(\gamma, p)$ is distributed according to a Lévy alpha-stable distribution with skewness parameter p and γ the stability parameter. This means that the distribution of the space increment has a long tail and decays as $|x|^{-1-\gamma}$. The space-fractional approach models distributions with non-Gaussian heavy tails in space due to the broad distribution of spatial transition length. This, however, leads to divergent second centered moment. This means the actual width of the modeled distributions is not finite. The phenomenology of this approach is based on a medium structure that is characterized by a power-law distribution of length scales, and transport mechanisms that allow for traversing an arbitrary space increment within a constant time increment Δt .

Conclusion/summary/outlook

Solute transport, defined here as the movement of chemicals in soils and groundwater aquifers, plays a central role in global biogeochemical cycling. Population pressures increase loading of wastes and other chemicals to the subsurface and soil degradation can impact food security. Solute transport affects the efficacy and fate of agricultural chemicals, the treatment and disposal of wastewaters and wastewater treatment products, and the fate of many other potential contaminants. Solute transport is also important for maintenance of safe water supplies, nourishment of plants, and many other processes.

Advection, diffusion, and dispersion are the three modes of solute transport and, depending on flow conditions, transport can be dominated by one or a combination of these. Retardation is a process that slows the movement of a solute. It results from the interaction of solutes with soil surfaces by physical or chemical adsorption. In many soil applications, where the transport of a uniformly applied chemical on the land surface to a water table may be of primary interest, a one-dimensional treatment of solute transport may be adequate.

The Advection-Dispersion Equation and its two-region or two-site enhancements have traditionally been applied to solve solute transport problems. Fitting to the Advection-Dispersion Equation has revealed that the dispersivity increases with the scale of the transport process. More recent models anticipate different types of scaling depending on the structure of the medium heterogeneity. Despite decades of intensive research in soil science, groundwater hydrology, and chemical engineering, our *a priori* capability to predict solute transport in complex porous media such as soils remains limited.

Abstract

Lysimeters are experimental systems for the investigation of water and solute fluxes in the complex soil-plant-atmosphere continuum. Innovations in weighing technology, in the control of the lower boundary condition as well as in data processing make lysimeters a representative ecosystem section that can map all translocation processes. However, the quality of the data is associated with a high technical effort and intensive, and regular maintenance. High precision weighable lysimeters represent the “gold standard” for determining water and solute transport, to calibrate and validate models and to improve process understanding in the critical zone.

Key points

- Lysimeters are an experimental system to control and monitor water and solute fluxes in soil systems.
- History of lysimeters, covering the period from the 1800s to the technological innovations made over the last 20 years.
- Lysimeter types, possibilities, and limitations
- Parameters and variables measured in lysimeters
 - Water transport
 - Solute transport
 - Plant (above and below ground)
 - Supporting lysimeter measurements
 - Site conditions
 - Operation of lysimeters
- Lysimeter can serve as a “Gold Standard”

Introduction

For many studies in the fields of soil and environmental sciences, such as hydrology, agriculture, ecology, meteorology, and the corresponding intersections of these disciplines, conventional field trials are unsuitable, as variables cannot be adequately controlled or measured experimentally. Particularly in the very complex soil-plant-atmosphere continuum, lysimeters represent

an integrative experimental approach that enables precise measurements of water and matter fluxes in combination with field-like conditions such as plant stands. The experimental conditions can be integrated into an ecological framework with realistic conditions to obtain data on in-situ-processes with limited bias.

Lysimeters are vessels of various dimensions filled with repacked or naturally layered soil preserving ecosystem properties. There is a holistic approach with lysimeters, because each compartment interacts dynamically within the biosphere (i.e., soil, water, flora, fauna, and atmosphere). For measuring the different components of the terrestrial water cycle, non-weighable or weighable lysimeters are used to measure soil water storage change, evaporation, actual evapotranspiration, drainage, upward directed water fluxes, precipitation, non-rainfall (e.g., dew) and irrigation water. Only with weighable high precision lysimeters can all the terms of the water balance equation be measured directly (e.g., Forstner et al., 2021; Groh et al., 2019). A special feature of these high precision lysimeters is the direct determination of the hydrological interactions between soil, plant, and atmosphere.

The matter fluxes can be precisely balanced using lysimeters because the volume of the soil or the ecosystem section is exactly defined (Fig. 1). The advantage of balancing is used for investigations on the fate of fertilizers, pesticides, or other anthropogenic substance inputs, which can be measured in the percolation water. Observations on water and matter fluxes in lysimeters provide very reliable data sets for calibration and validation of ecosystem models on different scales (Schelle et al., 2012; Groh et al., 2018b).

Lysimeters can be used in a laboratory, greenhouse, climate chamber or integrated in natural or managed ecosystems. They may also be integrated into Ecotron ecosystem analyzers to produce a fully balanceable and controllable experimental facility (Roy et al., 2021).

History

The term lysimeter is derived from the Greek word “lysis,” that means “solution, dissolved” and the Greek word “metron,” that means “to measure.” Lysimeter experiments have been conducted and published in literature for 300 years. In the 18th century, the first lysimeter studies were carried out in the Netherlands and France. These had more the character of large-scale pot experiments than of modern lysimeter approaches used today. The studies in those early days were primarily aimed at determining the soil water balance and the consumption by plants. A comprehensive overview of historical lysimeter experiments is provided by Kohnke et al. (1940) and Goss et al. (2010). In the last 20 years, several innovations have been introduced into lysimeter technology that have significantly advanced measurement accuracy, directly measurable target variables, realistic integration of lysimeters in ecosystems, lysimeter filling, and data processing. The website of the Lysimeter Research Group (LRG) provides a broad overview of European lysimeter stations representing the different stages of technical development, with various historical, and technical information (www.lysimeter.at/lysimeterplatform.html).

Lysimeter types, possibilities, and limitations

As a general definition, a lysimeter consists of a vessel filled with soil. The lysimeter vessel can be placed above ground or inserted into the ground (Fig. 1). If larger weighable lysimeters are used, the lysimeters at field sites must be placed in a container to allow the installation of load cells. The different lysimeter types (Table 1) can be classified according to the following criteria:

- Size
- Filling procedure
- Design
- Bottom boundary condition of the lysimeter

The size of a lysimeter has considerable significance for its functionality and, depending on its size, may capture soil and plant heterogeneity of the experimental site. The dimensions of lysimeters should therefore be based on the processes to be investigated and the spatial situation, so that processes as well as their spatial variability or heterogeneity can be represented by the selected size. Therefore, under conditions with large soil and plant heterogeneity, it is recommended that the size of the soil core should be greater to encompass the heterogeneity. However, the size of monolithic filled lysimeters is limited by the technical feasibility. For example, large-scale lysimeters with soil volumes of >12 cubic meters require enormous technical effort to establish (Fig. 2). The size and shape of a lysimeter (soil surface, depth, round or square) should be adapted to the type of vegetation. To avoid dominance of flowerpot effects of preferential root growth along the lysimeter walls, there must be a minimum depth or volume of soil that allows natural root development by the vegetation.

The surface areas and depths of lysimeters used worldwide vary enormously in their dimensions and there are no uniform standards. Commercially available lysimeters vary in size from very small, weighable lysimeters (so-called smart field lysimeters) with a surface area of 0.07 m², to larger (0.25 m²) and deeper 0.30–0.90 m (down to 3.0 m depth) lysimeters (Riedl et al., 2022). Purpose-built lysimeters with a surface area of 1–3 m² and depths between 1.0 and 2.5 m, which are also weighable and filled with soil monoliths, are widely used (Marek et al., 2006; Pütz et al., 2016; Allen et al., 1991). With disturbed filled soil, lysimeters can be produced in any size, with dimensions that allow the investigation of entire forest ecosystems or artificial hillslopes. The Landscape Evolution Observatory at biosphere 2 hosts three artificial weighable lysimeters with dimensions of 330 m² and 1 m depth to study hillslope processes under controlled boundary conditions (Arevalo et al., 2020). Other non-weighable lysimeters with surfaces up to 660 m² and depths up to 5.0 m have been built and operated for decades (e.g. Britz, Eberswalde, Germany, St. Arnold; Colbitz-Letzlinger Heide, Germany; Glugla et al., 1982; Wyrwich and Brandenburg, 2018).

The filling procedure is the transfer of a representative soil section of an ecosystem into a lysimeter. A distinction must be made here between filling with disturbed or monolithic soil cores. In disturbed soil cores, soil is repacked into the lysimeter to form layers mimicking the natural horizons found in the field. The disadvantages of this method are the high effort, the disturbed soil structure, the artificial bulk density of the soil, and the stimulation of mineralization processes through the aeration or loosening of the soil. For monolithic lysimeter filling, a distinction is made between the preparative procedure, the cutting method, and the milling method (Fig. 2). In the preparative method, a soil monolith is carved out of the undisturbed soil according to the dimensions of the lysimeter vessel and then transferred into the lysimeter vessel. This method can be used for almost all soil type, especially very stony ones.

Table 1 Characteristics of different lysimeter types.

Type	Description and characteristics
Volumetric/drainage lysimeter	simplest, most common, lysimeter vessel is set up to collect and/or to measure the seepage water volumetrically, non-weighable, water fluxes measured indirectly by seepage water volume at the bottom, precipitation and/or irrigation by separate measuring instruments, various designs of the vessel bottom are used;
Gravimetric lysimeter	weighable lysimeter vessel in combination with a weighable seepage water tank, different weighing techniques available (mechanical, electronic, . . .) and different bottom boundary conditions, very expensive due to complex installation and construction; short measure intervals provide a direct measurement of the water balance components (i.e., precipitation, non-rainfall water, actual evapotranspiration and drainage)
Groundwater lysimeter	weighable/non-weighable lysimeters; characteristic is a device that adjusts the groundwater level in the lysimeter tank constantly or variably; external water addition is necessary during operation; measurement of groundwater recharge possible; use of monolithically filled lysimeters possible;
Large-scale lysimeter	dimensions approx. 15 m × 15 m × 3 m (length x width x depth) and larger, large lysimeter basins, usually made of concrete, filled with disturbed soil, non-weighable; undisturbed variants also possible, if impermeable soil layers are present, only lateral boundaries have to be drawn in; because of the size, special devices for measuring the seepage water are necessary; valid measurements after an adaptation period of 1–2 hydrological years; very expensive; investigation of large vegetation;
Smart field lysimeter	miniaturized form of a fully functional lysimeter, weighable, controlled bottom boundary condition, seepage water and upward direct water measurement, sensor installations;
Special lysimeter	to measure run-off and/or lateral flow

Fig. 2 Filling of 2 m², 2.5 m depth lysimeter with soil monoliths – cutting method: lysimeter with the lysimeter press on top (1st row left), pressing of the lysimeter completed (1st row center), two filled lysimeters and pushing the bottom plate under a filled lysimeter (1st row right), lift out the filled lysimeter (2nd row left), Insertion of a 2 m², 2.5 m long lysimeter into a lysimeter basement (2nd row center), and view into the lysimeter basement with lysimeters protruding through the basement floor, platform scales, and containers for drainage sampling (2nd row right).

In the cutting method, the lysimeter container is equipped with a cutting edge and then pressed into the soil with a centrally acting hydraulic cylinder (Figs. 3 and 4). Once the monoliths have been transferred to the lysimeters, a base plate is pushed underneath the lysimeter. In the milling method, a milling tool is placed on the bottom side according to the inner diameter of the lysimeter container and this tool, which works in a rotating manner, is then pressed into the soil together with the lysimeter container (Reth et al., 2021) (Fig. 5). The advantages of the cutting and milling methods are undisturbed soil structure and natural stratification. The disadvantages of monolith lysimeter filling are the lack of information on the integrity of the soil monolith and the fact that soils with high stone content cannot be filled in via cutting or milling. However, only monolith-filled lysimeters include the inherent heterogeneity of the soil that was present at the start of monitoring. But even with monolithically filled lysimeters, there are challenges to their longevity and accuracy at representing the surrounding environment due to the new boundary conditions they impose. Generally clayey soils cannot be investigated in long-term studies with lysimeters, as their shrinkage and swelling, depending on the soil water content, may prevent sufficient connectivity between the soil and the lysimeter wall. This can create artificial preferential flow paths along the lysimeter wall (wall effect).

The lysimeter design can be easily differentiated between cube-shaped, cuboid or cylindrical lysimeters. Due to the stability of the cylindrical shape, this is very well suited for monolithic filling. With the angular variants, deformation of the lysimeter vessel may occur or, depending on the soil type, soil compaction in the corners is possible.

Fig. 3 Filling of lysimeter - cutting method: careful pressing of a lysimeter vessel into the ground with four hydraulic cylinders and an excavator as abutment (left), preparation of the next driving section with inspection of the next section (center), sheared lysimeter was lifted out of the excavation pit for further processing (right) © G. Klammler, JR-AquaConsol, Austria.

Fig. 4 Reasonably priced lysimeter filling – cutting method: pressing and driving the lysimeter vessel into the ground with an excavator (upper row), shearing off the filled lysimeter with a bottom plate integrated in a transport frame (bottom row).

Fig. 5 Equipment for the vertical filling of soil monoliths with the milling method – starting the filling procedure, rotary cutting tool at the bottom of the lysimeter vessel (left), vertical filling procedure completed (mid), and bottom plate attached below the lysimeter and raising up the lysimeter (right) © S. Reth, UGT GmbH, Germany.

Fig. 6 TERENO-SOILCan lysimeter station Rollesbroich, Germany with six weighable, monolithic lysimeters in a hexagonal arrangement with a pluviometer (in the foreground) and a radiation sensor above a lysimeter (right side). The lysimeters can be recognized by the light-colored sealing lips that close the space between them and the lysimeter container against water penetration. In the center of the hexagon is the cover of the service pit.

Another constructive feature is the arrangement of lysimeters. Here, a basic distinction is made between the placement of a lysimeter in a slightly larger container (Fig. 1) or the installation in a basement-like building (Fig. 2). The lysimeter container completely accommodates the lysimeter vessel and the lysimeter surface is on an equal level with the surrounding field surface. The container requires a slightly larger volume to allow a temperature transfer from the surrounding soil into the lysimeter to be as interference-free as possible. This needs to be balanced against the space required to install the necessary equipment (load cells, brackets, cables, lifting device, etc.) to monitor environmental processes. The resulting gap is then closed by a suitable cover to exclude the intrusion of rain, soil particles or animals. However, this cover must not interfere with the measurements, such as the weighing. When installed in basement-like buildings, the structures have openings in the ceiling through which the lysimeters pass to the surface (Fig. 2). Often, the lysimeters are placed in the room on pedestals or similar, on which the weighing equipment is installed, and seepage water is recorded. The advantage of a lysimeter basement is the facilitated access to the lysimeters, so that maintenance as well as measurement operation are very easy. Disadvantages are the changed temperature profile in the lysimeters caused by the ambient air in the basement deviating from soil temperature and the high construction costs.

In modern lysimeters with a suction controlled bottom boundary, seepage water and rising soil water can be measured in a defined soil volume. To compensate for the hydraulic disconnection of the lysimeters, soil cores from the underlying soil layers, porous plates, or suction candles and tensiometers are installed at the bottom of the lysimeter and tensiometers at a similar soil depth in the surrounding field (Fig. 1 top, Figs. 6 and 7, Fig. 8, left). An adjustable control algorithm minimizes the matric potential difference between the lysimeter and field using a bidirectional pumping system to transport water upwards (capillary rise) or downwards (drainage) via porous plates or suction candles at the lysimeter bottom and seepage water tank (Fig. 9, Fig. 8 left). This technique ensures that the water dynamics of the lysimeter correspond to the observed field dynamics (Groh et al., 2016). As a variant, there are also groundwater lysimeters in which a hanging water column is used to set the groundwater depth at the selected level.

Table 2 Advantages and disadvantages of the different lysimeter properties.

<i>Properties</i>	<i>Advantage</i>	<i>Disadvantage</i>
General	water balance, matter fluxes measurable, actual evapotranspiration measurable; use of tracers long-term experiments experimental repetitions (by number of lysimeters); representative ecosystem sections; weighable;	no horizontal flow; expensive; not applicable to all soil types; limited size;
Free-drainage	low construction cost; no additional technical components necessary;	precipitation and irrigation are measured by independent rain gauges; no active controlled bottom boundary, no upward directed water flux laborious maintenance
Suction-controlled	nearly undisturbed field situation; seepage water measurable; capillary rise measurable; complete solute transport (up- and downward direct)	
Monolith	natural soil structure, natural porosity,	complex, expensive filling technology
Weighable	complete water balance measurable; high temporal resolution of the measurement;	expensive

Other lysimeter bottom boundary conditions have an artificial gravel/sand layer, a perforated plate, or an outlet at the lowest point of the bottom, where soils are exposed to the atmosphere (Fig. 1 – center and bottom). Under these bottom boundary conditions, seepage water only occurs when the soil above the bottom plate of a lysimeter is saturated (i.e., matric potential ≥ 0 hPa) and thus deviates in the most cases from the water dynamics in the field. In addition, temporary anaerobic conditions at the lysimeter bottom affect plants and the fate of solutes, which might not reflect conditions in the surrounding field and thus lead to biased observations of water and solute fluxes with lysimeters. Water fluxes change under these artificial boundary conditions because either water is temporarily more accessible to plants due to the nearly saturated soil zone or upward directed water flow (capillary rise) is neglected, both of which affect evapotranspiration processes (Groh et al., 2016).

The different characteristics of lysimeter types and the advantages and disadvantages of the several lysimeter properties are compiled in Tables 1 and 2.

Parameters and variables measured in lysimeters

Water transport

The essential advantage of a lysimeter compared to other experimental settings to investigate water and matter fluxes is the exact knowledge of its volume. At constant soil mass, the change in weight of a lysimeter can only occur by the water phase and to a very small extent also through the production of biomass. The respective components of the water balance are measured across the surface and bottom section of the lysimeter.

In the past, weighable lysimeters were used to determine the change in soil water storage (ΔW). Here measurement frequency was relatively coarse (>30 min) and thus actual evapotranspiration (ET_a) was estimated indirectly by solving the water balance equation:

$$\Delta W = P + I + NRW - SR - D - ET_a + CR$$

where all units are given in millimeters ($\text{kg m}^{-2} = \text{L m}^{-2} = \text{mm}$) at a given time and ΔW is the change in the lysimeter weight over a consecutive time step, P is precipitation, I is irrigation, NRW is non-rainfall water (i.e., dew, hoar frost, fog, water vapor adsorption), SR is surface runoff, D is seepage water, and CR is upward direct water flow from capillary rise (Fig. 9). SR and D will be sampled with a separate container which is either measured by a balance or mounted on the lysimeter itself. Whereby for the latter case, water balance can only be solved on the corresponding drainage sampling time step.

The use of external rain gauge measurements is a clear disadvantage as it neglects NRW and introduces, depending on the rain gauge design and functionally, a systematic measuring error for P , caused by wind and evaporation (Fuchs et al., 2001), when estimating ET_a . Due to high precision ($\leq 10 \text{ g m}^{-2}$) and high temporal measurements (≤ 1 min) with modern lysimeters, water balance components such as ET_a , P , and NRW can be measured directly, when assuming no simultaneous ET_a and P or NRW during a specific short time interval (e.g., 1 min.) with the lysimeter balance (Fig. 10). Collection of high-frequency measurements (< 1 min) is negatively affected by noise induced by wind when determining land surface water fluxes and require a noise reduction filter to be applied (Peters et al., 2017).

Fig. 10 Evaluation of the 72-h weight course of a lysimeter with a controlled lower boundary condition and separate recording of drainage: leaf wetness measured by a sensor (above); periods with dew, actual evapotranspiration (ET_a), and actual night time evapotranspiration (night ET_a) (bottom), measured at the TERENO-SOILCan lysimeter station Rollesbroich, Germany (Fig. 6).

In many regions, *NRW* inputs contribute additional water to precipitation to the ecosystems (Dawson and Goldsmith, 2018). *NRW* consists of dew (Kaseke et al., 2012), hoar frost (Groh et al., 2018a), distillation (Agam and Berliner, 2006), fog (Klemm et al., 2018), rime (Meissner et al., 2007), and water vapor adsorption (Saaltink et al., 2020). The different *NRW* fractions are typically small at the daily scale compared to precipitation amounts, but they provide a constant source of water and thus help in maintaining ecosystem functions. Despite the importance of *NRW* inputs in soils for terrestrial ecosystem, they are the least studied and characterized components and processes of the terrestrial water cycle. Weighable high precision lysimeters can be used to quantify all *NRW* inputs and their various fractions using other measuring devices (e.g., visibility and leaf wetness sensors; for more details see (Zhang et al., 2019)).

Thus modern weighable lysimeter systems with high precision and high temporal resolution of the weighing data allow direct measurements of ET_a , P , and *NRW* and equipped with a dynamic bottom boundary control provides an holistic determination of the hydrological interactions between soil and atmosphere (Fig. 1 - top; Fig. 6) (Pütz et al., 2016).

Solute transport

The fate and the translocation of a solute in a certain period can be balanced in a lysimeter. The solute can either be applied to the soil or based on a known quantity of the solute in the soil, factoring in biomass uptake and the natural input via the air pathway or volatilization. Solute flux can be measured with lysimeters only directly at the surface (i.e., amount of water) and at the bottom (i.e., water and solute). The measurement of the solute fluxes in the different soil layers of a lysimeter is only possible with additional, considerable effort since D and CR can only be determined indirectly compared to the solute concentration there. Lysimeters are often equipped with sensors at different soil depth to measure water content, matric potential, temperature, and chemical parameters (Fig. 9 right). The leached and upward directed solute flux (S_{flux} , $mg\ m^{-2}$) of modern lysimeter with dynamic controlled bottom boundary can be measured (Pütz et al., 2018):

$$S_{flux} = \begin{cases} C * D, & D > 0 \\ C * CR, & CR > 0 \end{cases}$$

with C the measured solute concentration in D or CR ($mg\ L^{-1}$).

Heat transport

To measure the water and material balances of the reference ecosystem in lysimeters as realistically as possible, no artificial temperature conditions may prevail. Lysimeters that are embedded in the soil should have a close horizontal and vertical connection to the surrounding, naturally layered soil. Especially in the case of weighable lysimeters, the air space between the

weighable lysimeter and the container surrounding the lysimeter should be kept to a minimum (Fig. 1). This facilitates the horizontal temperature transition between the surrounding soil and the soil in the lysimeter. The lysimeter materials that are exposed to the atmosphere (radiation) and are in direct contact with the lysimeter soil lead to a distorting effect on the soil temperature profile in the lysimeter. All lysimeter parts protruding above the soil surface must be as small as possible with a high albedo to minimize this effect. The main temperature changes occur via the surface of the soil in a lysimeter and cause natural temperature gradients within it, which then continue to depth. Horizontal disturbances of the heat flow caused by constructional deficiencies of the lysimeter system can lead to cone-shaped temperature profiles in the lysimeter soil, which means that the temperature profile in the center of the lysimeter corresponds to the natural profile. To a certain depth, the edge effects overlap the natural temperature profile and cause artificial temperature profiles. These effects can be particularly pronounced in lysimeters that are operated in basement lysimeter stations (Fig. 2, Fig. 11). Here, the lysimeter must be insulated to decouple it from the cellar climate. Ideally, the cellar temperature should be adapted to the ground temperature and, if necessary, additional temperature control must be provided via the lysimeter base (Podlasly and Schwärzel, 2013).

Plant (above and below ground)

The vegetation plays a pivotal role in the terrestrial water balance. However, transpiration measurements with weighable lysimeters are not directly possible, so further ecophysiological measurements are needed for a better understanding and modeling of the processes in the soil-water-plant continuum. Ecophysiological aboveground measurements include the canopy height, plant development stages, leaf area index, sap-flow, stomatal conductivity, photosynthesis, and soil respiration. In addition to recording the fresh mass or dry mass of the plants from a vegetated lysimeter, grain yield, single plant parts or their various components can also be balanced. Observational systems to measure root growth indirectly, such as by rhizotrons, can be included in the lysimeter design to include monitoring of the belowground activities of plants.

Supporting lysimeter measurements

The time scale of a lysimeter experiment (short-term or long-term) has an essential influence on the experimental setup. Here, especially in the initial phase of an experiment, so-called “priming effects” can occur. These are processes that have been unnaturally intensified by the lysimeter setup and thus lead to artificial results. In contrast to experimental approaches whose boundary conditions are artificially controlled (laboratory experiments, Ecotrons, etc.), the lysimeter in a field experiment is influenced exclusively by the natural boundary conditions. Due to the complex installation, lysimeter experiments tend to be designed as long-term experiments. Exceptions here are smart field lysimeters, which can be used more flexibly in the field due to their small size, fast soil excavation and operated by power from a solar panel (Eberbach et al., 2013). In studies on the fate of anthropogenic or natural substances under consideration of the water balance, at least two hydrological years or two seepage periods are used in humid climatic zones based on empirical values. In this period, a seepage water volume corresponding to two to three times the soil pore volume should be obtained to be able to describe the transport of these materials.

Fig. 11 Lysimeter facility with basement and control plot (in the foreground) and lysimeter in containers embedded in the ground surrounded by a fence and paved paths (in the background). Negative impacts of the surrounding environment cannot be excluded here.

The objectives of lysimeter experiments can be either specific questions or monitoring approaches that record processes or changes in ecosystem sections within the framework of long-term measurement series.

Site conditions

Lysimeters should be integrated into an ecosystem in such a way that no lateral influences, such as from trees, hedges, bushes, buildings, or fences, etc. in the immediate vicinity of the lysimeters can affect the measurements (Fig. 6, Fig. 7 – optimal, Fig. 11 – non-optimal). A lysimeter that is perfectly integrated into the ecosystem is indistinguishable from the surroundings and should also have a plant population or vegetation that corresponds to that of the surrounding environment. This means that vegetation on the lysimeter and the surrounding area is managed in a similar way (e.g., fertilizer, pesticides, growth regulator, plant density and rows etc.) to prevent an “oasis effect” (Allen et al., 1991). In the early work with lysimeters, it was already recognized that lysimeter construction requires the soil moisture of the reference soil outside the lysimeter to correspond to that inside the lysimeter (Fig. 8). The lateral separation of the lysimeter from its surrounding disturbs lateral in- and outflows. However, this limitation can also be used to determine such processes when comparing measurements within the lysimeter and the field, e.g., for lateral subsurface flow (Ehrhardt et al., 2021) or soil physical properties (Bravo et al., 2020).

A lysimeter interacts directly with its surroundings; changes in solar radiation, shading, the local wind field, and the surrounding crop have a direct effect on the measurement results of a lysimeter (Hagenau et al., 2015). The type of vegetation on a lysimeter, whether representing a natural or an agricultural ecosystem, or bare soil, will determine further management. In the case of agricultural land, soil cultivation, sowing, plant variety, fertilizer application, plant protection activities and harvesting of the surrounding area must be same as for the lysimeters.

Additionally, high-quality, sensitive precipitation gauges and weather stations, which record air temperature, wind speed, solar radiation, and humidity, complete a lysimeter station and enable a full data set to analyze or simulate ecosystems (Fig. 6).

Operation of lysimeter installations

Associated with a lysimeter experiment, a comprehensive number of soil physical, hydrological parameters must be recorded, preferably at high temporal resolution. A horizontal installation of probes should be established in the soil to avoid artificial preferential flow paths. To achieve a better understanding of water fluxes within the soil profile of a lysimeter, measurement of the matric potential and water content is recommended to determine the soil water retention characteristic. However, consideration must be given to the possibility that installed probes can influence processes of the soil water flux (e.g., disturbance of the pore space, interruption of flow paths). The measurements can be compared to water retention curves obtained from soil cores sampled close to the lysimeter.

Suction cups have been used in experiments on the fate of organic or inorganic substances in lysimeters, such as plant nutrients, pesticides, or other anthropogenic chemical inputs (Fig. 12). The management of the soil water sampling strategy (applied pressure head, sampling frequency) might have an effect on the transport water and solutes (Weihermüller et al., 2007).

Fig. 12 Additional measurements and work in lysimeter experiments: Measurement of plant height (left), sampling of soil solution (center), and seepage water (right).

Of course, any maintenance activities or ancillary measurements carried out while the experiment is in progress should have minimal influence on the results of the study. This is a very special challenge, if not impossible, with high precision weighable lysimeters, because the very sensitive balances with an accuracy of approx. 10 g or less can be affected by wind, animals, and maintenance. To minimize disturbances of the measurements, recording the weighing results with the highest possible frequency is useful, with data then averaged and stored in manageable time units, such as every minute. All other measurement data should be recorded at least in 10-min intervals to document the dynamics of the various processes, from which, it may be deemed advisable to shorten the interval to detect the presence of fast processes and interactions.

Technical maintenance and control of a lysimeter is of central importance to the functionality and the quality of the results from a lysimeter experiment. In addition to the daily check of the actual measurement data, now more permissible via online access, a weekly on-site check can identify any external influences or faults. Furthermore, continuously recorded images of a camera on site can be very helpful for the data quality management and to document the seasonal vegetation development.

Only through this intensive control and maintenance work can complete and valid data sets be obtained, thereby allowing reliable and versatile analyses. In addition to the personnel costs for at least one technician, those for repairs or replacement of probes and measuring instruments must also be identified. As lysimeter experiments are often designed as long-term experiments, probe and sensor failures are to be expected with increasing experiment duration.

Lysimeter as a “gold standard”

Since lysimeters can be used to measure both the water balance and the mass balance of a selected variable, lysimeters have been considered for many years as the “gold standard” in various scientific fields. The prerequisite for all comparisons between the real field situation and the lysimeter is to ensure optimal experimental conditions of the lysimeter.

Weighable precision lysimeters are used to determine the actual evapotranspiration, although a variety of structural and experimental parameters can falsify the measurement results (Allen et al., 1991, Groh et al., 2019). When the experiences and technical innovations of Lysimetry described in this article are consistently implemented, lysimeters record the actual evapotranspiration highly precisely and can be used to evaluate the Eddy Covariance method (Gebler et al., 2015). Precision lysimeters are also used as a reference for the measurement of precipitation and non-rainfall water (Groh et al., 2018a; Haselow et al., 2019; Herbrich and Gerke, 2016).

Lysimeters were also used as a “gold standard” to assess the environmental fate of pesticides or nutrients. In addition to the fate of the test compounds (degradation, sorption, etc.), their soil transport has also been explored (Führ et al., 2003). Based on 34 lysimeter experiments with 28 pesticide active ingredients and 35 metabolites, simulation models could be evaluated (Hardy et al., 2008). The reduction of nitrate contamination in water catchment areas in combination with the use of models and appropriately coordinated agricultural management advice could also be achieved with the inclusion of lysimeter measurements (Klammler and Fank, 2014).

Groh et al. (2022) used the “Data set Classification software” developed by Kersebaum et al. (2015) to quantitatively analyze and classify a typical data set of high-precision weighable lysimeters for the calibration and validation of agro-ecological models. Their results classify the dataset with a score of >200 points as highly suitable for parameterizing and improving agro-ecosystems with models.

Observations from weighable, high precision lysimeters thus provide a holistic data set on the ecosystem and can truly be considered a gold standard that can be used either to calibrate and validate models or to improve process understanding in the critical zone.

Acknowledgment

The authors would like to thank Gernot Klammler (JR-AquaConSol GmbH, 8010 GRAZ Austria) for the figures and photos (Figs. 1, 8, and 3) and Sascha Reth (Umwelt-Geräte-Technik GmbH, 15374 Müncheberg, Germany) for the photos in Fig. 5. Abstract

The chapter highlights the achievements of notable scientists who have made considerable contributions to our understanding of soils.

Introduction

The technical chapters in this edition of the Encyclopedia of Soils in the Environment very clearly demonstrate the impact over the last 20 years that the application of new technologies has had on our knowledge of soil, the material from which, with sunlight, we derive our daily food. Although the varied characteristics of soil have long been recognized, it would be fair to claim that modern soil science started with Nicolaus of Cusa (1401–1464), who designed a theoretical experiment (in 1450) that Johannes Baptista van Helmont (1579–1644) carried out in what is claimed to be first quantitative experiment in history. He grew a willow tree (*Salix* sp., L.) for a period of 5 years in a pot of soil, enclosed with a perforated lid, and established that the plant removed water from the soil and there was little or no loss of soil solids (van Helmont, 1648). Building on this Stephen Hales (1677–1761) distinguished between the weight of water lost from the soil during the growth of sunflower (*Helianthus annuus*, L.) and the mass transpired (Hales, 1727), essentially separating transpiration through the plant from evaporation from the soil. Hales also estimated the quantity of water added to soil from dew. Philippe de la Hire (1640–1718), who is generally recognized as pioneering the use of lysimeters, and Edmond Halley (1656–1742), now more associated with astronomy and planetary motion, investigated the water balance following precipitation reaching the soil surface. Firstly, de la Hire (1703) demonstrated links between precipitation, drainage and plant water use and then Halley (1687, 1691), recognizing the large volume of water in the atmosphere, emphasized that a quantitative estimate of evaporation was essential to formulate the hydrological cycle between sea and land. However, Halley (1691) did not believe that rain (plus dew) was the source for all springs and rivers. John Dalton (1766–1844), now better known for his atomic theory (Dalton, 1805), also made use of a lysimeter in correctly establishing the components of the hydrological cycle and applying his understanding to derive a water balance for England and Wales (Dalton, 1802a). This required an estimate of the loss by evaporation (E) which he determined as a function of the temperature of the water and the vapor pressure of the atmosphere, together with wind speed such that

$$E = c (e^* - e)$$

where c is a factor depending on wind speed, e^* is the saturated vapor pressure at the temperature of the water and e is vapor pressure of the air over the period of observation (Dalton, 1802b). This provides an example of the development of a topic, in the period of the natural philosophers, that is so critical to the understanding of soil and ecosystem functioning in this era of climate change. In this chapter, the contribution of some past scientists to soils in the environment is recognized.

In the 1st edition of this encyclopedia, the biographical accounts of the activities of J.B. Lawes (1814–1900) and J.H. Gilbert (1817–1901), at what is now Rothamsted Research (Harpenden, UK) focused on their field-based investigations, which earned them recognition as the founding fathers of the scientific method in agricultural research (Johnson, 2005). What is not mentioned is their establishment of the first lysimeters built to retain the natural structure and profile of the soil and its use in determining the quantity and chemical quality of the deep drainage component of the soil water balance (Lawes et al., 1881a,b). The contribution of H. L. Penman (1909–1984), also at Rothamsted, to the science of evaporation of water from land, either cropped or uncropped and rainfed or irrigated, was described in the 1st edition of this publication by Monteith, who contributed to the equation for evaporation from cropped land that bears both their names. Penman's 1948 equation overcame contemporary equipment limitations to measurement of the temperature of an evaporating surface by combining thermodynamic and aerodynamic equations for heat and mass transfer from a surface, where water was freely available. The equation included a parameter

*Emeritus Professor of Plant Pathology.

representing the change in saturated vapor pressure with temperature, which could be treated as a constant over the range of temperatures involved in most systems involving natural evaporation.

The contribution of Monteith (1929–2012) was to extend the Penman formula for application to vegetation (Monteith, 1965). His approach was to rewrite the Penman formulation in a form applicable to single leaves, developing the idea that diffusion from saturated surfaces within leaves was a component of the transfer pathway of water to the atmosphere. This required addition of a parameter to describe stomatal restriction of the diffusion of water. Another parameter was required to represent the external diffusion resistance controlling the flux of water vapor from the leaf driven by the vapor pressure difference between the leaf surface and the free atmosphere. This modified Penman equation has become known as the Penman–Monteith (PM) equation. In 1998 it was taken up as the basis of a globally valid standard for crop water requirement calculations for the Food and Agriculture Organization (FAO) of the United Nations (Allen et al., 1998). The FAO PM equation has the form that only requires meteorological data as input and the predicted evapotranspiration applies to a hypothetical crop, 0.12 m tall, having a fixed canopy resistance and albedo. It is envisaged as resembling an extensive area of green grass of uniform height, that completely shades the soil and has an adequate water supply. It has also become the standard approach to establishing irrigation needs (Allen et al., 2023).

In 1967, Monteith was appointed Professor of Environmental Physics in the School of Agriculture at Nottingham University, creating a strong team with both teaching and research responsibilities. The research had a dual focus: first, microclimate and carbon balance of barley crops, including physiological, agronomic and hydrological components; second, the physics of the animal environment, particularly animal heat balance. In 1976, the work on microclimatology was extended to include tropical crops. Based on the notes for his greatly appreciated class lectures, Monteith published the highly influential text “Principles of environmental physics” in 1973, which extended to four editions, the last three being jointly authored with Michael Unsworth (now Professor Emeritus, College of Earth, Ocean and Atmospheric Sciences, Oregon State University). Some 20 y after moving to Nottingham, during which he served as Head of the Department of Physiology and Environmental Science (1970–73 and 1979–82) and Dean of the School of Agriculture (1985–86), Monteith took up the position of Director of Resource Management Division at the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) in Hyderabad, India. His responsibilities also extended to outstations, including one in Niger in the sub-Sahel. Monteith effectively changed the way in which agronomists and crop physiologists considered the influence of weather on dry matter production by focusing on solar radiation, temperature and humidity. First, the rate of crop dry matter production was proportional to the rate at which a crop canopy intercepted radiant energy (the radiation use efficiency, e), when light was a major limiting factor, with crop yield being a linear function of the cumulative radiation intercepted over the growing season. Second, the dry matter produced per unit of water transpired (transpiration efficiency, q) is almost proportional to the mean value of the saturation vapor pressure deficit of the atmosphere (D) to which the canopy is exposed during the day.

Monteith then introduced the concept of normalized rainfall or irrigation (P_n), where

$$P_n = \frac{P}{D} \cdot D_0$$

P is the rainfall or irrigation in mm and D_0 is the normalizing factor, which has the same units as D (for D in kPa, $D_0 = 1$ kPa).

The dry matter produced per unit of water transpired can be similarly normalized and the slope of the ratio $j = e/qD$ provided a new climatic index and could be used to estimate the potential rate of transpiration (E), rather than by summing a radiation term and an aerodynamic term, as in the Penman equation.

The rate of dry matter accumulation per unit area is given by qE and by efS , where f is the fraction of solar radiation, S , incident per unit area

$$efS = qE$$

$$E = fjSD$$

Monteith plotted normalized monthly rainfall, j^* , against incident radiation over the same time period and indicated on the graph the relationship for a constant value of j per MJ m^{-2} . He argued that during those months where values of normalized rainfall, j^* , exceeded the value of j , crop production was energy limited but when j^* was less than j , it was water limited.

When water was limiting, Monteith's contribution was to demonstrate how crop transpiration depends on the rate at which the root system grows down and proliferates within the soil profile. The period available to the crop for growth is dependent on both soil and climate.

John Monteith was born on the west coast of Scotland but moved to Edinburgh at the age of eleven. Quietly spoken and friendly, he had a great sense of humor. At one workshop on thermocouple psychrometry led by his friend Gaylon Campbell, Monteith circulated a spoof menu for the dinner, offering “Campbell's soup, Welded joints à la Wescor (the main manufacturer at the time), with a sweet of chromel caramel (chromel is an alloy much used in thermocouple manufacture) with cooling currants all washed down with Sauterne Chateau Spanner” (Spanner had been a major proponent of thermocouple psychrometry) (Fig. 1). He is also reported to have jokingly attributed the origin of *albedo* to a fictitious American astronomer, Al Bedo, whom Monteith described as studying the reflectivity of stars!

Organic matter content is a critical component of soil, being crucial for structure, the chemistry and biology that underpin its functioning and associated ecosystem services. However, the chemical investigation of the material as a whole was based on its extraction from soil using a strong alkaline solution (now typically sodium hydroxide at pH 13) that was subsequently protonated

Fig. 1 Menu composed for dinner at a workshop on soil psychrometers by John Monteith.

to enhance its solubility. There have been a number of additional assumptions about the nature of soil organic matter (SOM) that have been associated with the analysis of the extracted material, including its recalcitrance and hence long residence time in soil. It has also been assumed that SOM has been formed following microbial breakdown of plant and animal remains, and the decomposed material being subject to secondary synthesis of compounds of large molecular weight under the influence of metals or extra-cellular enzymes. Recent assessments indicate that most of this picture of SOM chemistry is wrong, and only the role of soil microorganisms remains as key focus (Lehmann and Kleber, 2015).

The development of our understanding of the overall dynamics associated with SOM and the organisms involved owes much to Sir Edward John Russell (1872–1965), working first at Wye College, the School of Agriculture of the University of London, and then at Rothamsted. His research in the early years of the 20th Century provided new and broader understanding of microscopic soil organisms. His starting hypothesis was that the oxygen absorbed by uncropped soil was a measure of the total activity of microbes involved in decomposition processes and the release of plant nutrients. He devised a method to determine the uptake of oxygen into soil and used it to show that the rate of utilization in various soils of similar type (clayey, sandy, calcareous) correlated with

their fertility. Furthermore, this rate was greater in surface soils where conditions of temperature and moisture were more likely to encourage microbial activity. However, oxygen uptake was greatly reduced after autoclaving the soil at 130 °C for 30 min, supporting the claim that it was the microorganisms that were creating the oxygen demand.

Serendipitously, when a temperature of only 95 °C was accidentally used instead of 130 °C, the rate of oxygen uptake into soil greatly increased instead of reducing. In collaboration with F.V. Darbishire, Russell followed up this observation of the effect of incomplete sterilization, and was able to obtain similar results after heating soil to 100 °C or treating it with volatile biocides (Darbishire and Russell, 1907). Importantly, they investigated the growth of plants in pot experiments comparing the effects of the incomplete sterilization of soil with untreated soil from the field. Growth was better and the uptake of N, P and K was greater in pots containing the treated soil; a result attributed to changes in the microbe population. Similar heat (95 °C) and biocide treatments also resulted in a considerable increase in the formation of ammonia as well as in bacterial numbers (based on plate counts) relative to the untreated control soil (Russell and Hutchinson, 1909). They attributed their results to the removal by the incomplete sterilization of a 'harmful factor' that limited the number and activity of soil bacteria. The factor was likely an organism or group of organisms that were bigger than and predatory on the bacteria, possibly protozoa that were larger and more susceptible to the treatments, and their absence would allow the large increase in number and activity of the soil bacteria. Russell and Hutchinson suggested that the ciliates and amoebae present in untreated soil fitted the experimental evidence. Their premise was that soil normally contains an active population of protozoa that prey on the bacteria, but which are more readily killed by partial sterilization, and this further stimulates the beneficial activities of the bacteria into quicker release of plant nutrients.

The discovery that soils typically contained a wide range of different active microorganisms opened up a new field of research within soil science. But Russell was keen to apply research findings to practical agriculture. Recognizing that it was not a practical option for arable agriculture and aware that soils used in the glasshouse industry had a limited life before they developed 'soil sickness' and became unusable for cucumber or tomato production. The nature of the phenomenon was investigated on commercial operations in the Lea Valley on the northeast fringe of London. The soils were found to have very limited bacterial activity, releasing very limited amounts of plant nutrients. However, partial sterilization of the soil again resulted in the stimulation of the bacteria with protozoan predation being the suspected cause of the 'soil sickness'. Heat or biocide treatment became standard practice for maintain good growing conditions and an industry-sponsored research station was established to support growers.

As already noted, the partial sterilization treatment affected the nitrogen available in the soil, which stimulated a survey of seasonal fluctuations in the NO_3^- -N content of field soils together with linked data on weather, soil treatment and cropping. Russell and A. Appleyard then attempted to relate bacterial numbers to the decomposition of organic matter and the formation of CO_2 and NO_3^- -N in the soil. Plate counts of bacteria were made, and the content of NO_3^- -N and CO_2 determined in soil and soil atmosphere, respectively, from five plots on experiments at Rothamsted at a two-week interval over three cropping seasons. Russell and Appleyard argued that the fluctuations in numbers of bacteria matched those for CO_2 and NO_3^- -N, sufficiently to indicate a causal relationship, with temperature and rain being the main factors controlling microbial activity.

Scarcity of fertilizer materials and the imperative for greater food production in the British Isles during World War 1 increased the requirement for organic amendments, such as animal manure and composts. Russell then developed practical schemes for the formation and use of organic amendments, which he identified as contributing to improved soil structure, providing food for the beneficial soil microbes as well as their activity providing the nutrients required by plants. From this effort, two publications resulted: "A student's book on soils and manures" (Russell, 1915) and "Manuring for higher crop production" (Russell, 1916). Both went into second editions by the end of hostilities in 1919! His most well-known publication, entitled *Soil conditions and plant growth*, was first published in 1912 and he wrote 7 editions before his son E. W. Russell produced three more editions, the last in 1973. Since then, there have been two more versions, one in 1988 edited by Alan Wild and the other in 2013 jointly edited by Peter J. Gregory and Stephen Nortcliff.

Russell was forced to give up his education at a technical school in Birmingham at the age of 14, when his family moved to London. Understanding that chemistry (a favorite subject) was practiced in chemists' shops (pharmacies), he opted to work in one and save money that he could use to go to college. He was quickly disillusioned by the reality of his duties but embarked on educating himself by reading and attending lectures and enrolling in courses at the newly-opened philanthropic venues for education and culture. After 3 years his father moved the family to Yorkshire and Russell, unable to find work with a chemistry link, first assisted in his father's Unitarian Chapel before embarking on a course in Wales to become a non-conformist minister. There his education was guided by the college Principal, who encouraged Russell to study for examinations that would eventually end in an open scholarship in science at Aberystwyth University. This he achieved in under 2 years. During his first year in Aberystwyth, he at last received direction in his scientific studies and, when he sat for the London Intermediate B.Sc., he came out top in chemistry and obtained an additional two-year scholarship. After his second year, Russell transferred to Owen's College, Manchester, where his two mentors gave him expert tutelage in chemistry. At the end of his second year at Manchester, he was awarded his B.Sc. in Chemistry and was then appointed Lecturer and Demonstrator. His post-graduate research was on the rates of explosion in gases and the reduced reactivity resulting from desiccation of some combustible gas mixtures, for which he was awarded the degree of D.Sc. by London University.

Russell was aware of the poverty that many were experiencing, causing him to consider the possibilities for resettling the urban poor in rural areas and providing training necessary for them to become contributing members of society. It also made Russell reassess his own career direction, leading him to considered the chemical changes induced by microorganisms. As a result, he obtained a lectureship in chemistry at Wye Agricultural College, where he recognized that building a team of scientists and allowing them to apply their different disciplines to the investigation of soil, plants and animals, presenting their results in a way that could

allow experts, teachers and producers to use them, could help develop and improve agricultural practice. The possibility became a step nearer, when the Principal of Wye (A D Hall) became the Director of Rothamsted Experimental Station and subsequently in 1907 he invited Russell to become the 'Goldsmith's Company Soil Chemist'. Five years later, Russell was appointed Director to succeed Hall who had become a Commissioner of the Development Fund set up by the British Government to support the scientific development of afforestation, agriculture and fisheries. In the 31 years of his Directorship, Russell was able to increase the scientific staff from 6 to 70, with a similar increase in the number of support staff. He was able to oversee the purchase of the estate and the integration of the small experimental station at Woburn belonging to the Royal Agricultural Society. This allowed comparative studies on light sandy to the more clayey soils at Rothamsted. He put in place various arrangements to ensure that each department knew what the others were doing and encouraged cooperation between them. Russell also encouraged visitors to the station, including farmers, members of scientific societies and parties of schoolchildren. Individual visitors were accommodated for shorter or longer periods as 'voluntary workers'. Some came to discuss problems arising from their work or to learn some new experimental technique. Many people, especially from overseas, carried out research on a specific problem, often as part of their postgraduate studies.

Russell received the award of the Order of the British Empire in 1918, and was elected a Fellow of the Royal Society in 1917. In 1922 he was created Knight Bachelor.

In 1927 he was invited to a conference of the recently formed International Society of Soil Science, held in the USA, and decided to become more involved in such international activities, which he saw as helping some of the poorer countries to increase their food production. He was President of the International Soil Congress held at Oxford in 1935.

Russell's influence was not limited to Britain but included its colonies and other overseas territories for which it had responsibility. He became aware that there was little exchange of information on current research between local researchers and those in Britain, resulting in an over-dependence on US work and leadership. Following a conference he initiated, specialist information bureaux were established and added to the Imperial Bureaux of Entomology and Mycology, with the task of publishing abstracts of literature, produce monographs and to provide those seeking information with the relevant list of source publications appropriate for their research. This became the Commonwealth Agricultural Bureaux in 1947 and CAB International in 1986.

In 1957, some 14 years after Russell retired, David Stewart Jenkinson (1928–2011) began working at Rothamsted Experimental Station. After gaining first-class honors in Experimental Science for both BA and BSc degrees, he remained at Trinity College, Dublin and took his PhD in organic chemistry. After a short period in industry Jenkinson decided on a more academic approach to science and obtained a 3-year appointment in soil science at the University of Reading, investigating the chemical structure of 'humic acids' in soil organic matter. He quickly realized that even using the cutting-edge methods of the time, including electrophoresis and infra-red or ultra-violet spectrometry, the nature of the formation of humic materials and their linkage with mineral surfaces meant their composition was likely to be extremely variable. However, his efforts were not without reward as Jenkinson and his colleagues, Goulden and Tinsley, were able to demonstrate for the first time that humic material contained peptide bonds but there were no chemical signatures for lignin. These results refuted the hypothesis then being advanced that the compounds were lignoproteins. Jenkinson also learned from Tinsley how important was painstaking attention to detail in quantitative analytical chemistry! Throughout his career he passed on this lesson to all who worked with him.

Jenkinson began his career at Rothamsted with a study the decomposition and turnover of organic matter in soil incubated under ambient conditions in bottles buried upside down in an unplanted field. He first had to develop the means of uniformly labelling plant material with ^{14}C and of determining the amount of label remaining in the soil after periods ranging from weeks to years. He solved both challenges, designing a growth chamber into which $^{14}\text{CO}_2$ could be introduced and developing new techniques to determine the ^{14}C remaining in the soil. He was able to show the rapid breakdown of both root and shoot material over the first year, with little difference between them after the first 3 months, and slow decomposition over subsequent years. Jenkinson noted that the loss of carbon from the soil did not occur at a uniform rate throughout the year but reflected the temperature in the soil at 10 cm depth. Ten years later, working in Nigeria he and A. Ayanaba showed that the rate of decomposition in soil of similar clay content was four times faster under tropical conditions but followed the same trajectory as at Rothamsted. In addition to temperature, the soil water regime influenced decomposition, with the short-term rate being slower in the dry than in the wet season (Jenkinson and Ayanaba, 1977).

During the incubation experiments at Rothamsted, Jenkinson also started investigating the effects of "partial sterilization" of the soil on the decomposition of organic matter. In his classic 1966 paper he assessed the various hypotheses to explain the greater microbial activity that E.J. Russell had noted and others had continued to investigate. Jenkinson argued that the process used to effect partial sterilization of the soil might release previously unavailable organic matter but this could also result from the killing of some of the microorganisms present. Jenkinson's experiment consisted of mixing soil samples taken from his field incubation study containing ^{14}C -labelled organic material and subjecting the mixture to a wide range of sterilizing treatments of varying severity and then determining the carbon dioxide (CO_2) evolved during incubation, adding a 1 mL suspension of fresh soil as inoculum.

The treatments ranged from air-drying at 20 °C to autoclaving at 120 °C, γ -irradiation, fumigating with alcohol-free chloroform (CHCl_3) or bromomethane (CH_3Br), or oven drying at 80 or 100 °C for 24 h. In all treatments the total amount of CO_2 evolved during incubation increased relative to untreated (Control) soil as did the labelled $^{14}\text{CO}_2$, with the two fumigant treatments resulting in a greater proportion of $^{14}\text{CO}_2$ than the others and being more than threefold that of the control. Diluting the soil oven-dried at 80 °C with fresh soil had no effect on the $^{14}\text{CO}_2$ evolved. Jenkinson concluded that this latter result was inconsistent

with proposed hypotheses about partial sterilization being associated with the presence of toxins in fresh soil, to prey-predator impacts, or to the changed presence of antagonistic microbial relationships. The results from all treatments were also inconsistent with hypotheses of changed availability of previously protected organic material, changed susceptibility to breakdown or to increased vigor of a surviving population following partial sterilization. The only “reasonably satisfactory explanation” was that the increased flush of CO_2 after partial sterilization was due to the decomposition of microbes killed by the treatment. Jenkinson then carried out some additional studies, using repeated partial sterilizations and showed that this initial conclusion was justified and that only a very small part of the $^{14}\text{CO}_2$ evolved came from a constant background production; heat and irradiation make some parts of the soil organic matter (both microbial and non-microbial material) more susceptible to decomposition but partial sterilization treatments generally do not prime non-microbial organic matter for decomposition. Killed or damaged microbes decompose more quickly than those unaffected.

With this background Jenkinson then developed the concept of a method to determine the quantity of C held in living cells in soil, termed the microbial biomass, requiring a treatment to “give complete or near complete” sterilization but does not change the susceptibility of non-microbial organic matter to decomposition and leaves no residues. He settled on chloroform fumigation as this was easier to use than bromomethane. Then by determining the increased CO_2 released by fumigation relative to untreated soil (F), the microbial biomass (B) is given by:

$$B = \frac{F}{k}$$

Where k is the proportion of microbial biomass carbon that decomposes in the post treatment incubation, which he determined experimentally for the ammonia oxidizing bacterium *Nitrosomonas europaea* as approximately 0.3 (based on a 10-day incubation at 25 °C).

The value for k suggested in Jenkinson (1976) was 0.5, taking account of a wide range of organisms. The method was investigated in detail by Jenkinson and Powlson (1976), in part stimulated by criticisms of the underlying assumptions made by E.A. Paul and colleagues in Canada – an example of scientific disagreement leading to additional in-depth investigation.

The limitation of the method for use as a monitoring or survey tool was clearly the long incubation time. Later work that Jenkinson undertook with Brookes and Vance, led to the introduction of extraction of chloroform-released organic-C using 0.5 M potassium sulfate (K_2SO_4) as an alternative to 10 days incubation.. Although the comparison with an unfumigated control was important, other than in very acid soils, and less carbon was extracted than released as CO_2 , the procedure took hours rather than 10 days. Subsequently the fumigation-extraction method has been very widely used. The estimate of microbial biomass carbon was robust and the basic technique could be adapted to determine the biomass nitrogen (Brookes et al., 1985) with 0.5 M NaHCO_3 at pH 8.5 being used as the extractant for the phosphorus content of the biomass (Brookes et al., 1982).

In 1978 Jenkinson, in collaboration with J.M. Oades at the Waite Agricultural Research Institute in Australia, recognized the potential of determining the energy present in biomass by its adenosine-triphosphate (ATP) content. The main problem was the ability to extract ATP from cells without its breakdown and the nature of the relationship between ATP and the microbial biomass present. Jenkinson and Oades (1979) solved the problem of the extract, adopting 0.5 M trichloroacetic acid (TCA), coupled with 0.25 M disodium hydrogen orthophosphate (Na_2HPO_4) and 0.1 M 1,1'-dimethyl-4,4'-bipyridylium dichloride (paraquat) (now replaced by 0.6 M Imidazole), where Na_2HPO_4 and paraquat serve to prevent ATP from becoming fixed to negative and positive charged sites in the soil during extraction.

Other extractants appeared to remove less ATP than did TCA, which also correlated well with the biomass estimated by the post-fumigation CO_2 flush determination. Results have also indicated that despite being a population that is largely inactive because of limited substrate availability, it maintains ATP levels that are more typical of actively growing populations in laboratory culture. There is no evidence that ATP from roots in soil being sieved prior to microbial biomass determination contribute to the total extracted.

Jenkinson made important contributions to the understanding of the nitrogen cycle in agricultural fields, particularly in constructing a nitrogen balance for the long-term arable experiment on Broadbalk at Rothamsted, recognizing the very significant contribution from the atmosphere as wet and dry deposition and encouraging its direct measurement. He also used ^{15}N -labelled fertilizer to identify that which was quickly taken up by the crop and that which entered the soil organic matter, observing its long-term fate, identifying losses to the environment via the drainage system as well as the factors that reduced fertilizer use efficiency. Similar investigations were aimed at understanding the fate of N under permanent grass.

The information gained was put to use in developing computer models that could help advise the agricultural community, both on managing N (the SUNDIAL model) and on managing soil organic matter (the RothC model). The latter has been widely adopted for use in conjunction with global and regional circulation models to identify effects on soils and their productivity as well as what changes in inputs might be required to maintain carbon stocks.

Born in Beverley Hills, California, Jenkinson moved to a small farm in County Armagh, Northern Ireland when he was 4 years old after his parents' fortune was adversely affected by the Wall Street crash. He was kindly, supportive to many scientific colleagues and quietly spoken until roused. He rarely gave direct instructions to his junior collaborators but if he “strongly suggested” a course of action he would be distinctly annoyed if it was not followed! He read widely and had interests in Irish folk music. It is possible to hear him talk of his experiences in a recorded interview at <http://cadensa.bl.uk/uhtbin/cgisirsi/?ps=aCwKfzqhqr/WORKS-FILE/172200051/18/X246/XTITLE/Professor+David+Jenkinson+interviewed+by+Paul+Merchant>.

In recognition of his research achievement Jenkinson was elected a Fellow of the Royal Society in 1991 and received Massey Ferguson National Agricultural Award in 1993 for his research on nitrogen fertilizers. He was elected an Honorary Member of the Soil Science Society of America in 1995 and of the British Society of Soil Science in 2007. He retired from Rothamsted in 1988 after 31 years.

Prof. Dr. Klaus Domsch (1926–2022) was an outstanding scientist with very broad human and scientific interests, who enhanced environmental sciences by bridging microbiology, plant physiology, soil science, biogeochemistry, and agroecology. His contribution to the development of soil biology as individual branch of science is impossible to overestimate.

Born in Chemnitz, he attended the princely school and “St. Afra” boarding school in Meissen. In 1944, at the age of 18, he was drafted as an auxiliary in the German Luftwaffe. After receiving an ‘emergency Abitur’, he trained as a mountain infantryman in Innsbruck. In 1947 he enrolled at the Humboldt University in Berlin and initially studied teaching. In 1949, he transferred to the University of Göttingen to study phytopathology. In 1953, he obtained his doctorate at the Institute of Plant Pathology. From 1954 to 1967, he held his first position at the Institute for Cereal-Oil Fruit and Forage Plant Diseases of the then Federal Biological Research Station in Kiel-Kitzeberg.

Since 1967, the name Domsch has been closely associated with soil biology. That was when he founded and became Director of the Institute of Soil Biology at the Federal Research Centre of Agriculture (FAL) in Braunschweig. Up to his retirement in January 1991, he had authored several books and more than 165 publications. As head of the institute, he was particularly concerned with mentoring new colleagues through scientific stimulation, personal empowerment, regular “eye-to-eye” discussions and pointing out the possible perspectives. During the period of his 24-years as Director, the Institute of Soil Biology obtained a world-wide international reputation for its excellent research and broad networking activities.

From the first publication in 1953, Domsch focused his research on soil fungi, the influence of pesticides on soil micro-organisms and on microbial degradation of pesticides in soil. The research was summarized in several books including a “Compendium of Soil Fungi” (Academic Press, 1980), a book that was the bible for soil mycologists for many years and was cited more than 7000 times.

Domsch made a great contribution to soil biology with his instigation of physiological approaches for microbiology in soil research. In 1962 he introduced soil respiration as a basic parameter for environmental research and related the CO_2 evolved from soil to the activity of its resident microbes. This was a revolutionary step enabling quantitative estimation of soil microbial biomass by substrate-induced respiration (SIR method in cooperation with J.P.E. Anderson) (Anderson and Domsch, 1978); differentiation between fungal and bacterial activity (the fungal:bacterial ratio) and finally a development of an eco-physiological approach (Anderson and Domsch, 2010) based on microbial metabolic indexes – (the $q\text{CO}_2$ and $C_{\text{mic}}:C_{\text{org}}$ ratio). Visiting scientists came from all continents to study these new methods. Publication of eco-physiological approach was awarded as a Citation Classic in Soil Biology & Biochemistry in 2010. For his great contribution to international science, Domsch was awarded the Gregor Johann Mendel Honorary Medal for Merit in Biological Sciences by the Czech Academy of Sciences in 1995.

His far-sightedness influenced a whole generation of scientists who are looking to link excellent basic research and practical agriculture in the field of soil biology; something so very important today if we are to make agriculture more sustainable, but also efficient.

Klaus was in great demand internationally and developed close and productive research involvements in the Netherlands (Centraalbureau voor Schimmelcultures, Baarn) and the USA (University of California at Riverside and at the Department of Plant Pathology Oregon State University at Corvallis).

As a scientist, he took enormous pride in and responsibility for the results of his research. Socially he impressed by the depth of his intellect, inexhaustible energy, wisdom, kindness, and charisma.

Domsch was an unconventional man and scientist. His motto in life was “Carpe Diem” (seize the day!). He was a living demonstration to junior colleagues that scientific excellence and enjoying life are not contradictions. His personal celebrations were unforgettable: full of (scientific) discourse, culture (music) and joie de vivre - an incentive for youth. His deep-rooted beliefs in classical philosophy and his humor were Inspiring!

After his retirement in 1991, he investigated his family history and the complexities of genealogy replaced that of the soil microbial world. On February 25, 2022, one day after Russia's invasion of Ukraine, Prof. Dr. Klaus Domsch, died in Wittmar, Wolfenbüttel County, at the age of 96.

Barbara Gertrud Hedwig Mosse (1919–2010) completed a Diploma and BSc in Horticulture before obtaining a First class Honours BSc in Botany, the latter while working as an Assistant Chemist for the Lawes' Chemical Company. In 1944 she moved to the Pomology Department at the East Malling Research Station in Kent, where she worked on rootstock incompatibility. Her results were reported in a technical communication for the Commonwealth Agricultural Bureau (Mosse, 1962). She published her first paper on mycorrhizas based on work that also formed part of her PhD, awarded in 1956. The paper in the journal *Nature* (Mosse, 1953) consists of four short paragraphs and a composite of three micrographs showing the hyphal connection between a “fructification” and a strawberry root, an enlargement of the point of entry of a hypha into the root and the colonization inside the root. The last paragraph describes her current efforts to “to synthesize mycorrhiza under controlled (aseptic) conditions.” She states that she had produced typical mycorrhizal infections in seedlings grown in autoclaved soil in the test tube by taking spores from the sporocarp of a fungus associated with strawberry roots in the field. That was very much a break-through moment in the field of mycorrhizal research as prior to that time researchers could not even be sure whether the fungus they were observing was a mycorrhizal fungus. Furthermore, it allowed pot cultures of a mycorrhizal fungus to be established on different host plants. Now there was reason to separate spores from the soil to have access to different fungi. Mosse next established that mycorrhizal apple seedlings and clonal leaf bud cuttings were significantly larger than their non-mycorrhizal counterpart and recognized that this had implications for the nutrient levels in the soil and in the plants. The shoot content of not all nutrients were enhanced, with some such as copper, iron and potassium showing positive increases but manganese was reduced.

In 1960 Mosse transferred to Rothamsted Experimental Station. She continued to investigate the potential for inoculating plants with mycorrhizal fungi under aseptic and non-sterile conditions. The importance of early inoculation to obtain the greatest impact on growth was recognized for applicability in annual plants. The role that some bacteria (MHB) can play in helping mycorrhizal fungi enter a host-plant root was also identified.

Mosse surveyed plots on the Broadbalk experiment for spores of mycorrhizal fungi in 1961–2, 1966 and again in 1968. Together with G.D. Bowen from Adelaide She investigated soils from Australia and New Zealand, producing a key for identification of mycorrhizal spore types as well as assessing the conditions most conducive to the presence of spores. Moist conditions and well-worked soils, such as in gardens, and elevated nutrient levels were associated with fewer spores, but soils under natural vegetation were less numerous and diverse than in cropped land. They also concluded that where root growth and development was more sporadic there were more spores.

Much of the next decade was spent investigating the potential benefits from mycorrhizal inoculation. Several studies indicated that the benefits to the host plant could be attributed to the improved supply of phosphorus (P). In work with D.S. Hayman, it was confirmed using ^{32}P -labelling that the fungal partner did not access different sources of P compared with the host-plant roots but was more effective in absorbing it from soils with smaller concentrations and could capture it from outside the soil volume available to a root. In one experiment, there was some evidence that inositol could be a potential source, which later researchers have showed can occur if bacteria are available to break it down and release mineral P for the fungus to take up. Her work also demonstrated that increased concentrations of P and N in the soil could have negative effects on the level of colonization within the root, even to the extent of apparently excluding the fungus, which has been a major cause of concern and even for dismissing the relevance of mycorrhiza in intensively managed crops. The effectiveness of the fungus in supplying P varied between different hosts and fungi, results that subsequently have been extensively investigated by the research community in recent years. There was also evidence that the laboratory isolates were not always more effective than the indigenous mycorrhizal fungi. Mosse's work also foreshadowed the ability of roots to attract specific beneficial microbes from the bulk soil to the rhizosphere. She saw the potential for inoculation in parts of the world with soils with low levels of available P.

Another important aspect that attracted her attention was the potential for interaction between mycorrhizal fungi and rhizobia in N-fixing legumes. It was observed in one experiment on an acid soil that rhizobia only formed sufficient nodules when the plants had also been colonized by mycorrhizal fungi. This kind of information provided useful background when the significance of signaling between microbe and host plant as part of the symbiosis formation was being explored some 20-years later.

Mosse had many people visit her at Rothamsted to gain experience in her laboratory and one with a particularly significant outcome was with M. Giovannetti. Their paper (Giovannetti and Mosse, 1980) compared 4 methods for assessing the infection by mycorrhizal fungi in host-plant roots. The methods chosen were:

- 1 the Gridline intersect method. This was used to estimate the proportion of roots infected and the total length of root and counting the number of interceptions that stained roots made with grid-lines.
- 2 the Visual assessment. Quick estimate of what percentage of the root in the dish showed as stained. Both these methods could be done under a microscope.
- 3 Slide method 1. The roots were cut into 1 cm long sections and 10, randomly chosen, put on a single microscope slide and the length of stained root in millimeters determined for each root and the percentage of the total root calculated.

- 4 Slide method 2. On similar samples of roots the presence or absence of stain was recorded and then expressed as a percentage of the whole.

Both these latter methods were used under the microscope. The results were subjected to statistical assessment that allowed the minimum number of roots or root pieces needed to be used for each method to be determined as well as the sensitivity. In addition, Giovannetti and Mosse reviewed the potential sources of error in each method. It was the first time that the standardization of methodology for making the key assessment in such studies had been attempted.

Mosse managed to travel widely, obtaining several Fellowships that she took at the University of California, Berkeley (1956); the Department of Arboriculture at the University of Pisa, Italy (1960) and the University of Otago, New-Zealand (1966) and was Visiting Scientist in the CSIRO Division of Soils in Adelaide, Australia (1966). She gave courses on mycorrhiza in Brazil, Nigeria, Malaysia and Hawaii.

Nicolson and Gerdemann (1968) published an account of the mycorrhizal fungi identified as members of the genus *Endogone*, including a new species *E. mosseae* (now *Funneliformis mosseae*), named in her honor.

It is clear that she was very passionate about her work. When José-Miguel Barea was visiting Rothamsted, on being told he was working on phosphate solubilizing bacteria she was very clear that he should work on mycorrhiza. Her enthusiasm for the subject and her influence on colleagues around the world have, as one person stated "I believe that she was a fundamental pillar for the development of mycorrhizal research in Europe and throughout the world, at a difficult time, especially as a woman. I think she can be fairly considered as 'the mother of mycorrhizae'."

José-Miguel Barea (1942–2018) was a native of Granada and studied Pharmacy at the University of Granada but even before he completed his degree in 1965, he was working with microbes in the Department of Microbiology. He completed his PhD in Microbiology in 1968, and his thesis work laid the foundation for the further study in Spain of the application of microorganisms that promote the growth of plants by supplying essential nutrients. For both the quality and novelty of his work he was given an Extraordinary Degree Award by the University of Granada.

In 1972 Barea spent a few months working on phosphate solubilizing bacteria (PSB) at Rothamsted Experimental Station, where at one teatime he had a chance meeting with Barbara Mosse, who asked what he was doing. He replied that he was working with PSB. Her response was to tell him that he needed to work with mycorrhiza, which were much more likely to help plants improve their P nutrition. His subsequent focus on mycorrhiza was therefor somewhat accidental but he considered it a stroke of fortune.

Barea obtained a position at the Consejo Superior de Investigaciones Científicas (CSIC), Zaidin Experimental Station (called 'El Zaidin' by Barea). He developed the work begun at Rothamsted on the effects of diazotrophs on the growth of higher plants. The evidence suggested that in *Azotobacter paspali* there was no transfer of nitrogen to host plant roots but its enhanced growth was associated with the release of plant growth regulating compounds, such as auxins gibberellins and cytokinins. He then developed a rapid test using yeasts to identify such substances and went on to show that these microbial products were important in the early process of root colonization by the fungi and now known to be a key part of the process of establishing the symbiosis. Barea included mycorrhizal fungi in his studies and, linked to work with D.S. Hayman at Rothamsted, reported on possible synergistic interactions between the mycorrhizal fungus *Endogone* and phosphate-solubilizing bacteria in low-phosphate soils.

Retrospectively it is possible to identify three strands to his work on mycorrhiza: the interaction between beneficial fungi and rhizobacteria, the role of mycorrhizas in restoration of marginal and degraded soils and the biodiversity of mycorrhiza in natural habitats. The first of these developed from his early interest in PSB and the interaction between rhizobia and mycorrhiza (de Aguilar et al., 1979) which provided a basis for the use of microbes in the supply of nutrients and protection against root pathogens in sustainable crop production. One aspect was to enhance the supply of P from rock phosphate for plants by the joint use of PSB and mycorrhizal fungi. In one investigation it was found that although the inoculation of alfalfa (*Medicago sativa* L.) with the mycorrhizal fungus *Funneliformis mosseae* was more effective than the indigenous fungi, in combination they were even better. Another part of the focus was on enhancing the colonization of host plants using rhizobia as mycorrhizal helper bacteria and part was using mycorrhizal fungi to enhance the supply of P to support biological N-fixation by rhizobia, such as in non-crop woody legumes. The later aspect also contributed to restoring degraded land in semi-arid regions, including the Mediterranean basin.

Barea's interest in the restoration of degraded soil not only covered revegetation with fast-growing trees and shrubs but included improving soil structure through the use of mycorrhizal fungi and reclaiming soils contaminated with heavy metals, using mycorrhiza to protect plants from the toxicity. His investigations also led to an evaluation of the activity of indigenous mycorrhiza in desertified semi-arid land, which suggested that there was sufficient to support the recovery of vegetation cover. He also considered the potential importance of the protection provided by mycorrhiza against drought and studied their effects on preventing premature aging in plants under such conditions.

He developed a general interest in the conservation of endangered native flora found in Granada's Sierra Nevada, and in other natural habitats. It was typical that he would seek to evaluate the potential role for mycorrhiza, including their biodiversity. One of the products of this line of research was the identification of a new mycorrhizal fungus *Entrophospora nevadensis* (Palenzuela et al., 2010). Barea recognized that native mycorrhizal fungi from saline locations could be important in the recovery of areas affected by salinity in natural or agricultural environments. In the Cabo de Gata Natural Park, Barea investigated the community of AMF in the rhizosphere of *Asteriscus maritimus* L. a plant adapted to Mediterranean saline areas. He and his colleagues found from a sample of 40 plants, 30 AMF species belonging to three classes, five orders, nine families and 13 genera of the phylum Glomeromycota (Estrada et al., 2013).

Barea saw the significance the molecular era for mycorrhizal research, using it to combine his interests in the biodiversity of organisms with better understanding their potential functioning within their local habitat.

Barea served as the Head of the Microbiology Department and Vice-Director of the Institute between 1983 and 1987, and as Director between 1989 and 1998. He served as an advisor for the Joint FAO/IAEA (International Atomic Energy Agency) in Vienna, where he promoted the use of $^{15}\text{NO}_3^-$ as a tracer for nitrogen metabolism in microbial and plant studies. He was a charismatic and inspiring teacher and scientific leader.

Barea was an advisor for the International Foundation for Science (IFS), which is based in Sweden, and supports research and research training projects in developing countries – a project close to his heart.

He was elected to the Academy of Mathematics, Physics, Chemistry and Natural Sciences of Granada in 2004. In the same year, he was appointed as a distinguished Professor at the

University of Buenos Aires in Argentina. In 2013, he received the President's Medal from the University of La Frontera (Chile) in recognition of his outstanding contributions to the formation of advanced human capital at the institute.

Barea had the reputation of working hard and playing hard. He enjoyed singing and was a member of a folk group which performed at many of the meetings that he organized.

Vladimir Victorovich Zelenev (1961–2021) was a multi-talented scientist combining unique expertise in soil science, soil microbiology, ecological modeling and environmental ecology. His academic career spanned a wide range of topics in the course of time. He received his MSc in Agrochemistry and Soil Science with honors from the Faculty of Soil Science of Moscow State University in 1983. Zelenev successfully defended his PhD thesis entitled "Spatial and temporal fluctuations in bacteria, microfauna and mineral nitrogen in response to a nutrient impulse in soil" at Wageningen University in the Spring of 2004. He received several fellowships from the International Agricultural Center and from the Graduate School PE&RC for PhD research at Wageningen University. His research on the production and emission of various greenhouse gases from soils in natural ecosystems (Van Bruggen et al., 2017), including carbon dioxide (CO_2) and methane (CH_4), led to Zelenev being given a prestigious fellowship from the Austrian Government to work at the International Institute for Applied Systems Analysis at Laxenburg.

Zelenev was the first scientist to write a simulation model for oscillating populations of bacteria interacting with their substrate (Zelenev et al., 2000, 2005). The unique aspect of this model was the realization that predators or parasites were not needed to initiate wave-like fluctuations in bacterial populations. There were many models describing oscillations in predators and their prey, but regulation of bacterial densities by interaction with their substrate was new. Zelenev introduced the concept of readily utilizable substrate. He realized that oscillations would ensue if growth and death rate curves crossed over at a particular substrate level, referred to as "scissors."

Zelenev was one of the recognized experts in the field of modeling decomposition of organic matter (Shahbaz et al., 2017). He was one of few modelers who combined a bottom-up and top-down approach to simulating organic matter decomposition. This resulted in the model "BACWAVE-WEB" with the necessary detail at the base and yet sufficient functional groups in the food web to be able to test some hypotheses about the role of these groups in organic matter decomposition and mineral nitrogen release (Zelenev et al., 2006). The "BACWAVE-WEB" model has excellent potential to predict responses of microbial communities to a disturbance, which could be used to characterize soil health: oscillations with greater amplitudes indicating poorer soil health.

Zelenev was an amiable and helpful friend and colleague to everyone who crossed his path. He had vast knowledge and interests, yet he always remained a modest person. He was very fond of literature, art and classical music, was fond of mountain skiing. Zelenev had many friends all over the world. He sang well, played the guitar, he was pleasant to talk to, witty, with an amazing sense of humor. He was a dedicated researcher and teacher, always and anywhere.

INDEX

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization, and it is arranged in set-out style, with a maximum of four levels of heading. Location references refer to the volume number, in bold, followed by the page number. Page numbers suffixed by *f*, *b*, *ge* and *t* refers to figures, boxes, glossary and tables terms respectively. *vs.* indicates a comparison. **Bold locators** refers to main articles.

 deficiency, 3:562
 pollution, 2:113
 in soil, 2:507
 Zonal-azonal-intrazonal soils, 4:249
 Zonal soils, 4:14–15, 4:188–189, 4:399
 Zymography, 1:354

Encyclopedia of SOILS IN THE ENVIRONMENT

Volume Five: Soil Physics

EDITORS-IN-CHIEF

Michael J Goss

Professor Emeritus, School of Environmental Sciences, University of Guelph, Guelph, Ontario N1G 2W1, CANADA

Margaret Oliver

Visiting professor, Soil Research Centre, Department of Geography and Environmental Science, Russell Building, University of Reading, Whiteknights, Reading, RG6 6DR, United Kingdom.

SECTION EDITORS

Dr Evgenia Blagodatskaya

Dept. of Soil Ecology, Helmholtz-Zentrum für Umweltforschung GmbH – UFZ, Theodor-Lieser Str. 4, D-06120 Halle (Saale), GERMANY

Professor Adrian Unc

Boreal Ecosystems and Agricultural Sciences, Grenfell Campus, Memorial University of Newfoundland, 20 University Drive, Corner Brook, Newfoundland A2H 5G4, CANADA

Dr. Siobhán Staunton

INRA, UMR Eco&Sols, Montpellier SupAgro, bâtiment 12, 2 Place Viala, 34060 Montpellier Cedex 2, Montpellier, FRANCE

Professor Baoshan Xing

University of Massachusetts – Amherst, College of Natural Sciences, Stockbridge School of Agriculture, Environmental & Soil Chemistry, Program, 410 Paige Laboratory, Amherst, MA 01003, USA

Dr Karin Mueller

New Zealand Institute for Plant & Food Research Ltd., Ruakura Research Centre, Private Bag 3123, Hamilton, New Zealand

Professor Christina Siebe

Instituto de Geología, Circuito de la Investigación Científica s/n, Ciudad Universitaria, Ciudad de México, CP 04510, México

Professor Rupert Baeumler

Institute of Geography, Friedrich-Alexander-University of Erlangen-Nuremberg, Wetterkreuz 15, 91058 Erlangen, Germany

Dr Uta Stockmann

Soil Processes and Function Organisational Unit, CSIRO Agriculture and Food, Black Mountain, GPO BOX 1700, Canberra ACT 2601, AUSTRALIA

Professor Paul Hallett

Room 2.23, Cruickshank Building, School of Biological Sciences, University of Aberdeen, Aberdeen, AB24 3UU, UNITED KINGDOM

Professor Dani Or

Department of Environmental Systems Science (D-USYS), Institute of Biogeochemistry and Pollutant Dynamics (IBP), Soil and Terrestrial Environmental Physics (STEP), CHN F 29.1 Universitaetstrasse 16, 8092 Zurich, SWITZERLAND
